Polymerization and polymerization initiation. Polymerization reactions in a glow discharge may occur either in the gas phase or at the electrode surface. Since the rate of polymerization is closely related to the degree of monomer adsorption (see later), it is probable that polymerization occurs at the electrode surface; the electrode surface being (except in the initial stages) the polymer which is being deposited on the electrode. Also the rate of polymerization in a glow discharge is independent of pressure above a certain minimum (see Fig. 5), which again indicates a surface reaction: a gas-phase reaction is generally proportional to pressure.

The formation of active species, which initiate polymerization reactions, may also occur either in the gas phase or on the electrode surface. It is well known that electron bombardment of organic vapours in the negative glow of a discharge produces a wide range of species, many of which could initiate polymerization reactions by condensing on the electrode surface and reacting with the unactivated adsorbed molecules. However, the absence of polymer on other parts of the apparatus close to the discharge suggests that this type of reaction plays no significant part in the overall polymer formation. Also the fact that polymer films cannot readily be formed by passing vapours through a discharge and impinging the emergent gases on to a suitable surface tends to confirm the foregoing suggestion.

Bamford *et al.*[6] showed that many polymers, when submitted to the action of a high-frequency electric discharge (maintained in oxygen, nitrogen, hydrogen and argon), produce radicals characteristic of the polymer in a surface layer less than 1μ thick. These discharge-induced surface radicals are similar to those obtained by irradiation with X-rays or high-energy electrons and are capable

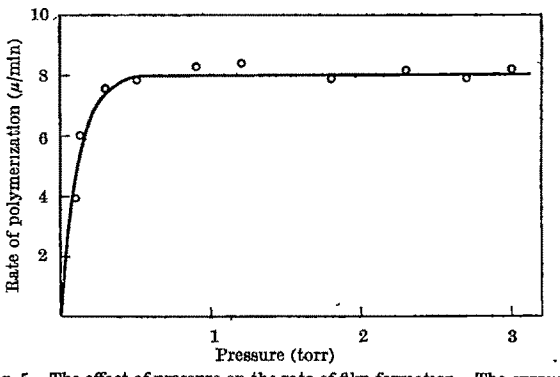

Fig. 5. The effect of pressure on the rate of film formation. The current density is 3·3 m.amp/cm²

of initiating polymerization reactions when exposed to the vapours of vinyl monomers.

The foregoing evidence suggests that active species are formed on the electrode surface rather than in the gas phase, probably as a result of ion or electron bombardment. With direct current, practically no polymerization occurs at the anode which indicates that the direct bombardment of electrodes by electrons plays no important part in polymer formation. Probably the sequence of events leading to polymer formation is as follows. Ions which are produced in the negative glow by electron bombardment of the vapour molecules are attracted towards the polymer coated electrodes. The primary step when an ion strikes the polymer surface is probably the same as in the case of high-energy radiation, that is, ionization or excitation of the polymer molecules followed by fragmentation resulting in active species which can propagate the polymerization reaction by addition of unactivated adsorbed molecules.

Adsorbed monomer molecules can also be activated by ions in a similar manner and this must happen when the first layer of polymer is formed.

Rate of polymerization and adsorption. The adsorption of a monomer at constant temperature on an electrode may be expressed by the relation:

$$x/m = \int (p/p_0)T$$

where x/m is the amount adsorbed and p/p_0 the relative vapour pressure, that is, the vapour pressure after adsorption divided by the saturated vapour pressure at the operating temperature.

In Table 2 the rate of polymerization of various monomers, determined at room temperature and pressures varying between 1 and 3 torr, are correlated with the amount of monomer absorbed on the electrode surface (p/p_0). Monomers with vapour pressures less than 3 torr at room temperature are not included for obvious reasons.

Clearly the amount of monomer adsorption on the surface of the electrode is extremely important in determining the rate of polymerization of various monomers in a glow discharge. Other factors must affect this rate, but presumably to a much lesser degree than adsorption. The results are not accurate enough to attempt a more quantitative correlation of these two parameters and also there is the added difficulty of taking into consideration the effect of other factors.

Some polar molecules with high dipole moments, such as acrylonitrile and vinylidene chloride, polymerize very rapidly even at low values of p/p_0. The explanation for the irregularity of these monomers is obvious and requires no comment.

The rate of polymerization of a particular monomer at room temperature and a fixed current density is, as already explained, dependent on the number of molecules adsorbed on the electrode. At low pressure ($p/p_0 \rightarrow 0$), this number is small and if there are enough ions striking the surface to allow every adsorbed molecule to react, then the reaction is proportional to the number of adsorbed molecules (that is, p, p_0 being constant). Above a certain saturation pressure the number of adsorbed molecules becomes so large that the number of active species formed is now dependent on the number of ions striking the surface. Under these conditions, the rate of polymerization is independent of pressure and is determined only by the current density. The effect of pressure on the rate of polymerization of styrene is shown in Fig. 5; the shape of the graph is somewhat similar to a normal adsorption isotherm as expected. The actual value of the saturation pressure is determined by the number of ions striking the surface, that is, by the current density.

Table 2. Variation in the Rate of Polymerization of Various Monomers with Adsorption

Rate of polymerization	Monomer	Approximate value of p/p_0
High	Styrene	0·2
	α-Methyl styrene	0·2
	Dicyclopentadiene	0 2
	Acrylic acid	0·2
Moderate to slow	Allyl alcohol	0·05
	Ethyl acrylate	0·03
	Methyl methacrylate	0·03
	Methyl acrylate	0 01
Slow to zero	Vinyl acetate	< 0·01
	Isoprene	0·002
	Isobutene	0·001
	Ethylene	0 001

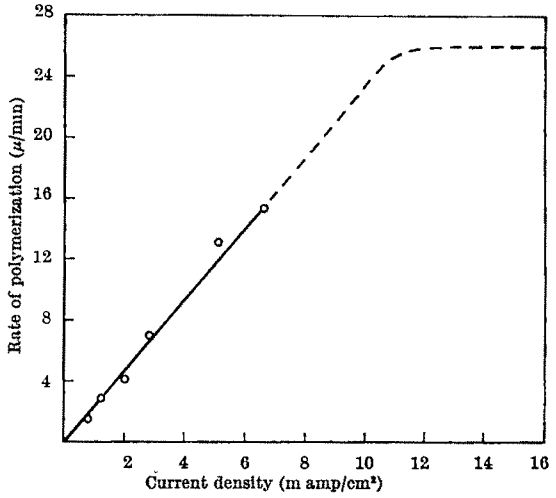

Fig 6. The effect of current density on the rate of film formation. The pressure is 2–3 torr

In Fig. 6 the rate of polymerization of styrene is plotted against current density; pressure is constant and above saturation pressure for all the current densities investigated. Under these conditions the rate of polymerization, as already explained, is directly proportional to the current density and may be expressed by the equation[7]:

$$m = \alpha I t$$

where m is the mass of polymer deposited per unit area, α a constant which varies with degree of adsorption of the monomer, I the current density and t the time of deposition.

If the current is further increased, a point is reached at which rate of polymerization is constant and independent of current density as shown in a broken line in Fig. 6. This flattening off of the rate-current density graph may be readily observed with styrene at lower pressures ($\sim$ 0·5 torr), where the saturation pressure is attained at a relatively low current density.

Another equation expressing the degree of adsorption of a monomer on an electrode is:

$$\theta = 1/[1 + (n/kp)]$$

where θ is the fraction of electrode covered with adsorbed molecules, k is a constant, p the pressure, and n the number of molecules evaporating off the electrode. At constant pressure the amount of adsorbed monomer clearly depends on n and hence varies with the temperature of the electrode. Therefore, monomers which polymerize slowly at room temperature should polymerize much more readily at lower electrode temperature. This was verified experimentally; for example, vinyl acetate, which polymerizes very slowly at room temperature, polymerizes very rapidly on an electrode at a temperature of $-30°$ C to give clear films of polyvinyl acetate.

All 'difficult' monomers would probably polymerize quite readily on electrodes maintained at a suitable temperature. For example, ethylene, which polymerizes very slowly at room temperature, would probably react quite rapidly on an electrode maintained at a temperature of about $-200°$ C.

Properties of glow-discharge polymers. Let the ratio:

$$\frac{\text{Number of adsorbed molecules}}{\text{Number of ions striking the surface}} = \varphi$$

At very low φ (because of a low p/p_0 or an unfavourable electrode temperature) the rate of polymerization is slow

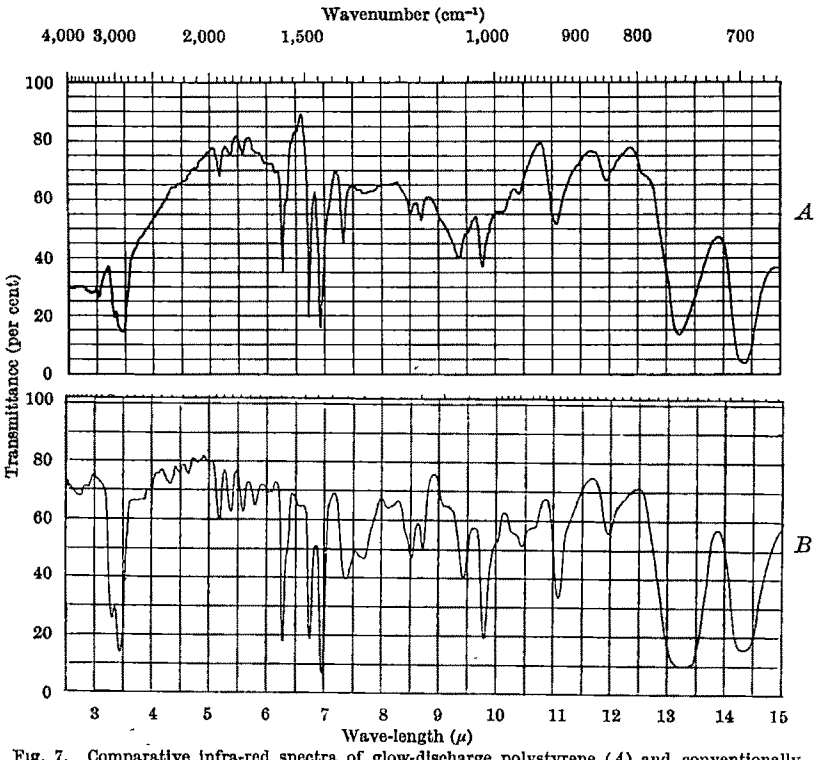

Fig. 7. Comparative infra-red spectra of glow-discharge polystyrene (*A*) and conventionally produced polystyrene (*B*)

and the films are coloured, highly degraded, insoluble and loosely adherent to the electrode. Under these conditions the number of ions striking the polymer surface must be far in excess of that required to allow every adsorbed molecule to react and thus a certain amount of film damage must occur. In the extreme with no adsorbed molecules the polymer is subjected to a continuous ion bombardment and must experience some radiation damage. However, a glow-discharge film subjected to an argon discharge for a prolonged period showed no visible signs of degradation, which suggests that ion bombardment is not primarily responsible for producing coloured, highly degraded films.

When φ is very large the number of active sites formed by ion bombardment is not sufficient to allow every adsorbed molecule to react. Under these conditions unreacted molecules become incorporated into the growing polymer, making it slightly tacky. However, on standing, these polymers slowly become hard due to the loss of trapped monomer; this latter process may be accelerated by moderate heating.

Clearly, for the best results the value of φ must be carefully selected. However, even under optimum conditions contamination of the polymer, as already indicated, proceeds by another mechanism.

Much information has been given in the literature concerning the species formed by hydrocarbon vapours in a glow discharge[8]. Electron bombardment of monomer molecules in the negative glow produces species ranging from carbon ions (C^+) to activated monomer. These species find their way to the electrode surface and either co-polymerize or become incorporated in the polymer. Co-polymerization of these species must produce a mixed type of polymer, and the differences between the infra-red spectra of glow-discharge polystyrene (Fig. 7) and ordinary polystyrene at 7·7, 7·8, 10·4, 13 and 15 microns and the significant background absorption of the former support this view[7]. Experimental evidence suggests, as expected, that the value of φ determines the degree of polymer contamination; at low φ the percentage contamination is high but progressively decreases with increasing φ.

Contamination of polymers by this mechanism may be minimized by lowering the concentration of monomer in the gas phase (that is, lowering monomer pressure) while still maintaining the concentration of adsorbed molecules at the desired level. This may be achieved by working in an atmosphere of monomer and inert gas; the monomer being present at very low partial pressure and the inert gas being added to keep the optimum glow-discharge pressure (1–5 torr). The degree of adsorption required may be achieved by selecting a suitable electrode temperature.

High monomer flow rate through the discharge is also beneficial in reducing contamination; this helps to reduce the amount of breakdown products from the discharge reaching the electrode surface.

Polymer films produced under optimum conditions are of excellent appearance, and are even and clear. The molecular weights of these polymers have not been determined since they are completely insoluble in most solvents. This suggests that all glow-discharge polymers are formed in a highly cross-linked state and that linear polymers cannot be formed by this technique. This is really to be expected if polymerization is initiated by activation of the polymer.

ALTERNATING CURRENT RESISTIVITY PROFILES THROUGH ANODIC OXIDE FILMS ON ALUMINIUM AND ITS ALLOYS

By Dr. G. C. WOOD and Dr. A. J. BROCK

Corrosion Science Division, Department of Chemical Engineering, Faculty of Technology, University of Manchester

THE elegant method of Heine and Pryor[1], namely measurement of the impedance of a barrier-type anodic oxide film during uniform thinning in a passivating alkaline chromate solution, has been used to obtain the a.c. resistivity profiles through such films formed on aluminium and its alloys in various electrolytes.

Specimens of annealed 99·99 per cent or 99·9999 per cent aluminium or of Al–Mg, Al–Zn or Al–Cu as single-phase solid solutions were etched for 15 min in 0·5 N sodium hydroxide solution at 20° C followed by a 1 sec dip in 50 per cent nitric acid at 90° C and washed. They were anodized at various constant current densities

(generally 10 m.amp/cm² or 100 μamp/cm²) in a flowing electrolyte at 25° C. Measurement of the balancing series capacitance and dissipation factor on specimens 0·2 cm² and 0·02 cm² in area during thinning in fresh 1 M sodium-chromate solution at 25° C (*p*H adjusted to 7·2), using a General Radio capacitance measuring assembly type 1610-*B*, permitted an area-independent calculation of the average resistivity of the film (also corrected for double-layer resistance[1]) at various stages. The reproducibility was within ± 5 per cent for all materials and for aluminium was within ± 3 per cent. The electrode potential during thinning was sufficiently high for the capacitance to give an accurate measure of film thickness during thinning. Electron microscopy with replicas and stripped films revealed uniform thinning on a sub-microscopic scale and a flaw density which remained constant during thinning and was generally too low to affect impedance measurements.

Fig. 1*a* and *b* show the average a.c. resistivities at 1 kc/s and 100 kc/s, respectively, obtained during thinning of 240 Å films formed in 20 per cent w/v $NH_4B_5O_8.4H_2O$ in ethylene glycol. The resistivity value plotted at each thickness represents the average value for the film of that thickness remaining on the specimen, not the

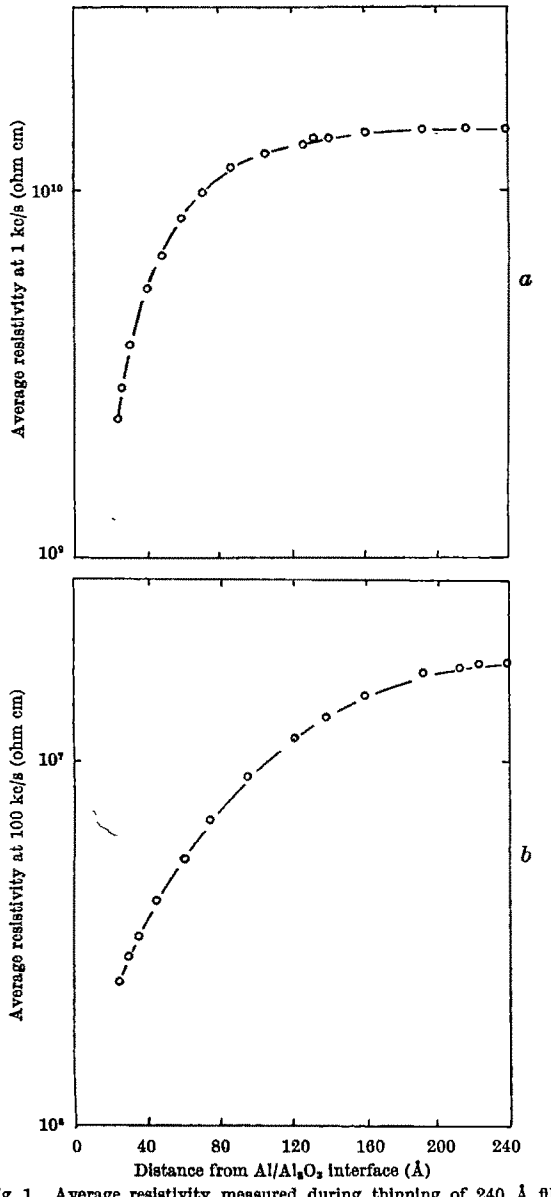

Fig. 1. Average resistivity measured during thinning of 240 Å film formed in ammonium borate in ethylene glycol. *a*, 1 kc/s; *b*, 100 kc/s

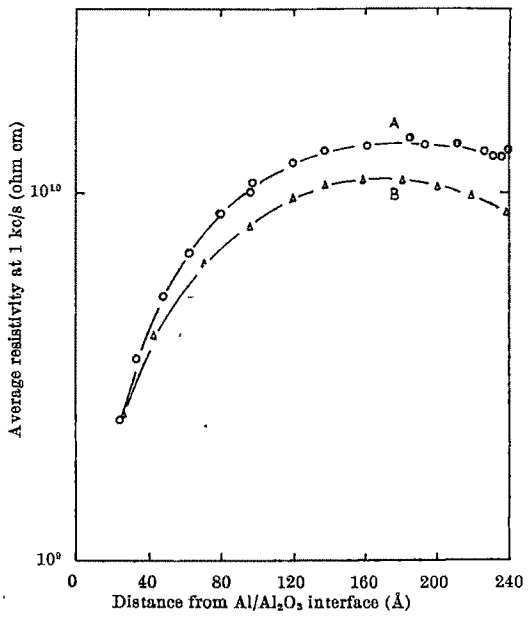

Fig. 2. Average resistivity at 1 kc/s measured during thinning of 240 Å films formed in 3 per cent w/v ammonium tartrate solution (*p*H 7) at: *A*, 10 m amp/cm², *B*, 100 μamp/cm²

resistivity of a small element of oxide in that location[1]. Films produced in this largely non-aqueous solution form with almost 100 per cent current efficiency in the range 1 μamp/cm²–10 m.amp/cm², contain a little boron but no water or glycol[2], and represent the simplest and most perfect films formed. The resistivity profiles depicted are independent of the current density of formation in the foregoing range and also of whether the current is terminated abruptly or allowed to decay slowly. They do not depend on the borate content of the electrolyte (5–25 per cent w/v salt) and therefore on the boron content of the film. There is no region towards the outside of the film where partial hydration has occurred[1]. When the results in Fig. 1 are plotted as balancing parallel resistances, R_p (obtained by multiplying the resistivity by the film thickness at each thickness), against thickness, a 60–80 Å-thick region of low resistance adjacent to the metal is evident at both frequencies. The Heine–Pryor theory predicts that this reflects primarily electronic relaxation processes, due to partially trapped electrons associated with O^2 ion vacancies or possibly Al^{3+} interstitial ions in the *n*-type oxide there. Furthermore, if R_p is plotted against the square of the thickness for this inner region, a straight line through the origin is obtained, indicating that the number of these *n*-type defects varies with the inverse distance from the metal interface[3]. This must represent a steady-state situation persisting for many hours and is not directly related to the conditions of film formation. Thus, Young has shown for tantalum that about 70 per cent of Frenkel defects rapidly disappear when the forming current is switched off[4]. The outer region of film where R_p increases linearly with thickness is said to be normal *n*-type oxide[1].

The resistivity profiles for films formed in aqueous electrolytes depend on the current density (and also possibly the time) of formation, and on the *p*H and anion, but are independent of small amounts of impurities in metal or electrolyte. Fig. 2*A* and *B* give the results at 1 kc/s for 240 Å films formed in 3 per cent w/v ammonium tartrate solution (*p*H adjusted to 7) at 10 m.amp/cm² and 100 μamp/cm² respectively, the values for 100 kc/s being identical with those in Fig. 1*b*. The results at 10 m.amp/cm² are very similar to those of Heine and Pryor, showing a partially hydrated region of low resistivity towards the outside and a very thin region of high resistivity at the outer interface. At 100 μamp/cm² this final region is not observed, possibly because of the more pronounced major

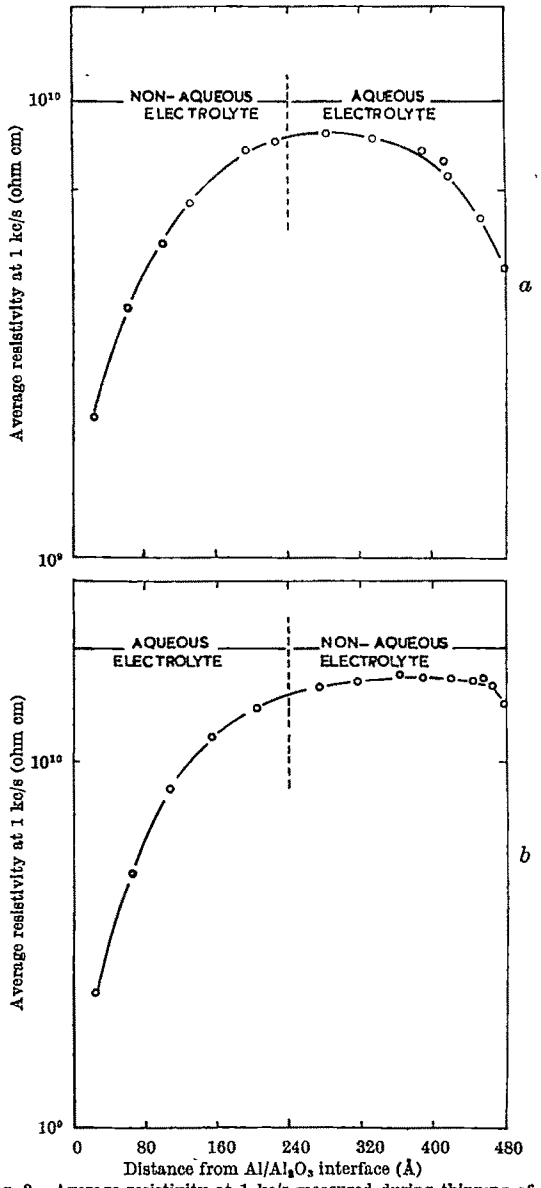

Fig. 3. Average resistivity at 1 kc/s measured during thinning of 480 Å duplex films formed at 100 μamp/cm² as follows. *a*, 240 Å in non-aqueous borate, 240-Å in tartrate; *b*, 240 Å in tartrate, 240 Å in non-aqueous borate

hydrated region of low resistivity. It has been suggested that the presence of the low-resistivity region at 1 kc/s but not at 100 kc/s is due to conductivity contributions from dipoles with relaxation times rather greater than 10^{-5} sec, possibly consisting of OH^- ions and their associated electrons replacing O^{2-} ions in the film[1]. There is some evidence from the curves that the inner regions of the film are also slightly hydrated. No pores could be detected in these films by electron microscopy. Change of tartrate *p*H in either direction from 7 increases the degree of hydration in the outer regions but the effect is greater at *p*H 9 than at *p*H 5. This possibly suggests that direct OH^- movement with the field is an easier and more effective process than indirect OH^- movement by way of a proton-portering mechanism, or than simple H^+ entry against the field[5,6], under comparable conditions. Both processes would tend to leave OH^- ions in the film. For *p*H values 6–8, the outer region of the resistivity curve is much lower for 100 μamp/cm² than for 10 m.amp/cm², but at *p*H 5 or 9 there is little difference and it is low in both cases. This suggests that where H^+ or OH^- ion activities are large their entry into the film by the appropriate mechanism is little affected by forming rate. The outer surfaces of films formed at *p*H 5 and 9 showed a few discrete pores and a general sponginess respectively. These phenomena, together with the likelihood of invisible pores in films formed at 100 μamp/cm², are natural extensions of the hydration processes described. For electrolytes at *p*H 7, the degree of hydration, generally but not always more noticeable at 100 μamp/cm², increases in the order borate, phosphate, tartrate and citrate. This is to be expected because it is well known that phosphate and to a lesser extent borate inhibit hydration of alumina at high temperatures. Presumably the main action of the anion is by adsorption on the surface but it may also compete with OH^- for entry and in some cases may supply the oxygen ions from which the film is composed. Electron microscopy showed that films formed in citrate are porous or heavily flawed, which means that the results of marker experiments of other workers using this electrolyte require re-appraisal. Addition of sodium chloride (up to 0·01 M) to tartrate forming electrolyte appears to give gross impurity substitution dipole effects of a type previously produced another way[7,8] and may also promote OH^- entry.

Fig. 3*a* and *b* show the resistivity profiles at 1 kc/s for duplex 480 Å films formed as follows at 100 μamp/cm²: *a*, 240 Å in non-aqueous borate, 240 Å in tartrate, *p*H 7. *b*, reverse order of *a*. The general conclusion is that oxide characteristic of the second electrolyte lies at the outside of the film, clearly favouring considerable cation movement. It is likely that this is the case for the non-aqueous borate but some OH^- movement (and possibly H^+ entry against the field) contributing to mass and current transport is indicated for tartrate. Thus, slight hydration of the inner borate-formed films occurs when tartrate anodization is carried out second. When the borate is anodized second the outer hydrated region of the initial tartrate-formed film must presumably be dispersed through the film, but there is some evidence of the most seriously affected region residing at the outside of the duplex film. Perhaps electrolyte can enter this very thin hydrated or quasi-porous region so that it does not take part in film growth. Detailed study of the results, to be reported elsewhere, also favours some O^{2-} ion movement.

Single-phase Al–Mg, Al–Zn and Al–Cu alloys, containing respectively less than 5 per cent magnesium, 2 per cent zinc and 4 per cent copper, give films with 100 per cent current efficiency in non-aqueous borate, but resistivity profiles show a reduction in resistivity through the film at 1 kc/s but not at 100 kc/s. This is presumably not due to OH^- entry but to Mg^{2+}, Zn^{2+} or Cu^{2+} ions (which have been shown by electron-probe microanalysis to enter films in their alloy proportions) in the film. According to the Heine–Pryor theory this would again seem to indicate dipoles which lose their effectiveness at rather less than 100 kc/s but alternative explanations are being considered. The effect is independent of current density. This is not so for films formed in the aqueous tartrate, where the effect is superimposed on that produced by OH^- ions in the film. The curves for films on Al–Zn are lower than those for Al–Cu or Al–Mg under these conditions.

Details of this investigation will be published later, together with a more critical appraisal of the theory and interpretation.

We thank Prof. T. K. Ross for providing facilities and for encouraging this work and the Science Research Council for a maintenance grant to one of us (A. J. B.).

PALAEOMAGNETISM AND POTASSIUM-ARGON AGES OF SOME VOLCANIC ROCKS FROM THE GALAPAGOS ISLANDS

By Dr. ALLAN COX and Dr. G. BRENT DALRYMPLE
U.S. Geological Survey, Menlo Park, California

SCIENTISTS of the Galapagos International Scientific Project visited the Galapagos Islands in January and February of 1964. As part of this project, rock samples were collected from 45 lava flows on thirteen of the islands. Our objective was to learn something about the ages of the rocks of the Galapagos Islands using potassium–argon dating and palaeomagnetic stratigraphy. The palaeomagnetic method for correlating young rock strata is based on the fact that the Earth's magnetic field has two stable dipolar states, a normal one during which the global field direction is toward the north, as at present, and a reversed state during which the field is directed toward the south. Lava flows contain ferromagnetic minerals which, like tiny magnets, become polarized when the flow cools. Thus, lava flows have a magnetic memory and record whether the geomagnetic field was normal or reversed at the time the flows originally cooled. They therefore may be grouped by age in sequences of normal or reversed polarity.

Locations of sampling sites and polarities of remanent magnetization are shown in Fig. 1. From six to eight oriented core samples were collected at each site, using a water-cooled diamond drill. Standard techniques were used for orienting the cores and measuring their remanent magnetization; these permit the direction of magnetization of the flow to be determined with an accuracy of 3°–4° (ref. 1). The magnetic stability of one core from each flow was tested in alternating fields up to 800 oersteds and was found to be of the type acquired by lava flows as a result of cooling in the Earth's magnetic field.

From previous investigations of volcanic rocks from other parts of the world, the following potassium–argon time scale has been found for the changes in polarity of the Earth's magnetic field[2–4]: 0·0 million years; Brunhes normal polarity epoch; 0·85 ± 0·15 million years; Matuyama reversed polarity epoch; 2·4 ± 0·1 million years; Gauss normal polarity epoch; 3·35 ± 0·1 million years; Gilbert reversed polarity epoch; where the (±) figures are subjective estimates of the range of uncertainty in epoch boundaries. In addition, there have been much more brief polarity periods which are important for purposes of detailed stratigraphic correlation but which will not concern us here[2]. Our correlation of lava flows from the Galapagos Islands will be based on their relation to the foregoing polarity time scale.

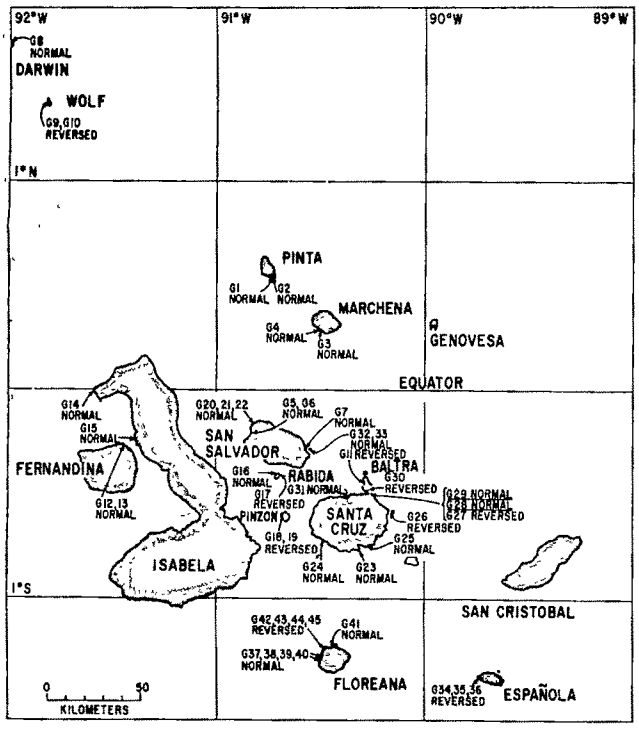

Fig. 1. Sampling sites and magnetic polarities

An ambiguity arises in correlating rock strata by polarity because the geomagnetic field has only two stable states. Thus a lava flow of normal polarity may have formed either during the Brunhes normal polarity epoch or during an earlier normal epoch. For young rocks, this ambiguity may be reduced by relating polarities to geomorphological indicators of age, such as the amount of erosion, the extent of faulting, and the development of vegetation cover. In Alaska, for example, we have found that primary volcanic features such as volcanic craters and flow surfaces are still recognizable in rocks as old as the beginning of the Brunhes normal epoch, but are almost completely obliterated in rocks formed during the Gauss normal epoch. In the Galapagos Islands, which are both arid and free from frost, such erosional differences are less pronounced.

All the sampled lava flows, which, from their state of preservation, appeared to be extremely young, are normally magnetized. A few of the reversely magnetized flows also are surprisingly young in appearance. The reversed flows on Pinzón, for example, occur on the walls of a crater that still retains its original form. On geomorphological grounds, however, most of the reversed flows appear to be older than the normal group. Those on Wolf, Baltra, northern Santa Cruz and Española Islands are exposed along high sea cliffs, some of which are faulted. The reversed flows on Floreana are from low volcanoes that have been partly destroyed by wave action where they face the sea.

We have used potassium–argon dating in conjunction with palaeomagnetic stratigraphy to provide additional information about the age of the rocks of the Galapagos Islands and to help in placing some of these lava flows in the correct polarity epochs. This dating method, which utilizes the constant decay of radioactive potassium-40 to argon-40, is the only known radiometric technique that can be applied to volcanic rocks that crystallized in the time interval of the polarity epochs outlined here.

The age analyses of this investigation were carried out on holocrystalline whole-rock samples of basalt. Typically, analyses on basaltic lavas that contain glass or alteration products do not give reliable age data. Therefore, the ten rocks for this investigation were selected only after thin sections had been analysed petrographically to ascertain that they were suitable for dating by the potassium–argon method. The argon analyses were carried out by standard isotope dilution techniques and the potassium determinations by flame photometry. The data from these analyses and the resulting calculated ages are given in Table 1.

The uncertainties in most of the age calculations are greater than is usual for rocks of this age because some of

* Calculated using $\lambda_\varepsilon = 0{\cdot}585 \times 10^{-10}$ yr.$^{-1}$, $\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr^{-1}, and $^{40}K/K = 1{\cdot}19 \times 10^{-4}$ moles/mole. The ± figures are the estimated standard deviation of precision.

the Galapagos rocks are abnormally high in contaminating atmospheric argon and most of the lavas have a low potassium content. However, for eight of the samples the dates are sufficiently precise to make it possible to assign the flows to polarity epochs. Even the results from the two flows with no detectable radiogenic argon are useful, because a maximum possible age can be found from the minimum amount of radiogenic argon that could have been detected in the presence of the observed atmospheric argon. In particular, the 1·32 million-year maximum age for the reversed lava from site *G17* precludes this flow from being assigned to any reversed polarity epoch other than the Matuyama.

Stratigraphic correlation of the flows collected on the different islands is given in Table 2. Flows not directly dated are correlated with other dated flows on the basis of geomorphologic and stratigraphic relations and on the basis of magnetic polarity.

Of greatest interest from the point of view of the history of life in the Galapagos is the time that each island emerged from the sea. Three considerations make it necessary to be cautious of interpreting the present results as being indicative of the sequence in which the islands emerged. On some islands, an older core may be completely masked by a shield of young lava, so that the time of emergence of the island cannot be determined geologically. Secondly, we were unable to sample the oldest exposures on some of the islands in the time available. Finally, some of the rocks that we sampled may have formed beneath the sea much earlier than the appearance of the first land.

However, even with these limitations of the present results in mind, several generalizations are apparent. The first is that most of the volcanic terrain exposed above sea-level on the Galapagos formed during a remarkably short interval of several million years. This follows from the observation that most of the lava flows were extruded during the Brunhes and Matuyama polarity epochs, which span the time from the present back to 2·4 million years.

The present results also have a bearing on Wilson's theory[5] that islands form over the mid-oceanic ridges,

Table 2. Assignment of Sampling Sites to Polarity Epochs

Polarity epoch	Island [sampling site*]
Brunhes normal polarity epoch	Isabela [*G14**, *G15*] Fernandina [*G12*, *G13*] Pinta [*G1*, *G2*] Marchena [*G3*, *G4**] San Salvador [*G5*, *G6*, *G7*, *G20*, *G21**, *G22*, *G32**, *G33*] Rabida [*G16*] Santa Cruz [*G23**, *G24*, *G25*, *G28**, *G29*, *G31*] Floreana [*G37*, *G38*, *G39*, *G40*, *G41*] Darwin [*G8* ?]

? Assignment to epoch uncertain.

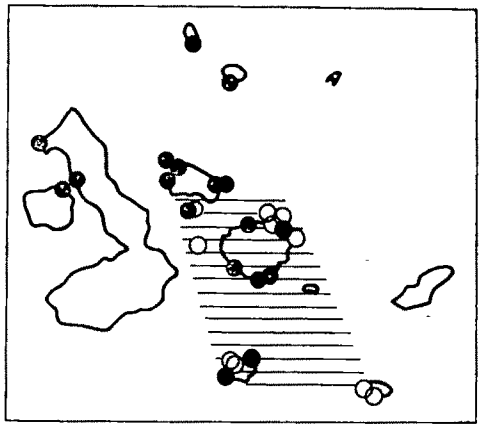

Fig. 2. Age relations among the 45 sampled flows. Shaded area contains all flows older than the Brunhes normal polarity epoch except for those on Wolf Island (off the diagram to the north-west). Solid circles are flows of the Brunhes normal polarity epoch and open circles are older flows. Adjacent flows of the same polarity are shown with one symbol

which are assumed to be topographic expressions of the upwelling limbs of convection cells in the Earth's mantle. Volcanic islands are assumed by Wilson to be active as they form over a ridge, then to become extinct as they are carried away from the ridge. In an archipelago formed this way, lava flows spanning the entire time of volcanic activity will not be found superimposed on one island. Rather, lava flows of increasingly older age will be found on islands progressively farther from the ridge. Immediately north-west of the Galapagos, there is the Cocos Ridge, which is an offshoot of the immense north–south East Pacific Rise. Thus the inferred direction of movement of the Galapagos would be toward South America, and the oldest islands would be at the south-east end of the chain. In Fig. 2, flows older than the Brunhes normal polarity epoch are indicated as open circles, and these may be seen to lie within the shaded area, which, in a general way, is at the south-east part of the archipelago as predicted. However, rocks of this older group also occur on Wolf Island, which is at the extreme north-west end of the chain. Moreover, the oldest rocks occur on the northern coast of Santa Cruz, which is near the middle of the chain. A further difficulty is that both young and old lava flows are found on many islands, such as Santa Cruz, where the oldest flows of the Galapagos and some of the youngest are closely juxtaposed. The age relations thus appear to form a more complicated pattern than that anticipated by Wilson's theory of oceanic island formation.

RELEASE OF TRITIATED BRETYLIUM BY SYMPATHETIC NERVE STIMULATION

By Dr. JOSEF E. FISCHER, VIRGINIA K. WEISE and Dr. IRWIN J. KOPIN

Laboratory of Clinical Science, National Institute of Mental Health, Public Health Service, U.S. Department of Health, Education and Welfare, Bethesda, Maryland

BRETYLIUM is a sympathetic blocking agent which has been used in the treatment of hypertension[1]. This drug does not interfere with conduction of the nerve impulse by the sympathetic nerve fibre[2], nor does it prevent the action of administered norepinephrine[3]. Sympathetic blockade after bretylium treatment appears to be a consequence of failure of the sympathetic nerve ending to release norepinephrine in response to the nerve impulse.

It has been suggested that replacement of norepinephrine by an inactive counterfeit transmitter molecule may explain the partial sympathetic blockade seen after α-methyldopa[4] and metaraminol[5], and the tachyphylaxis in response to some sympathomimetic amines[6,7] and chronic administration of monoamine oxidase inhibitors[6,7].

Since bretylium accumulates in sympathetic nerves[8], releases norepinephrine[9], and interferes with subsequent release of norepinephrine by nerve stimulation[9], it was suggested that this drug may play a part similar to false neurochemical transmitters[7]. In the experiments to be described, the release of tritiated bretylium, administered *in vivo*, from the isolated perfused cat heart and spleen was examined during sympathetic nerve stimulation.

Bretylium was tritiated by catalytic exchange (New England Nuclear Corp., Boston, Mass.) and purified by paper chromatography.

Eight cats received 80 μc./kg bretylium-^{3}H intramuscularly. 20 h later the splenic circulation was isolated using a modification of the technique of Brown and Gillespie[10] previously described[6]. The organ was perfused with Krebs–Ringer solution saturated with 95 per cent oxygen–5 per cent carbon dioxide (containing 100 mg heparin plus 1 g glucose/l.) and the splenic nerve was stimulated using a Grass Model 4 stimulator, with impulses of 1 msec duration and supramaximal voltage. Fluid in the spleen was expressed by nerve stimulation with 100 impulses (10 impulses/sec) 20 and 25 min after the start of perfusion. After 30 min, samples of splenic vein effluent were collected during consecutive 2-min intervals. Following two control intervals, the splenic nerve was stimulated with 300 impulses, at frequencies of 10–100 i.p.s.

Splenic contraction without nerve stimulation was induced by injection of 10^{-7} g *l*-norepinephrine into the splenic artery (at *NA*, Fig. 1). To block splenic contraction, 5 mg phenoxybenzamine hydrochloride was infused into the splenic artery; 10 min later, the stimulations were repeated.

Stimulation of the splenic nerve in the isolated perfused cat spleen resulted in increased amounts of bretylium-^{3}H in the effluent perfusate (Fig. 1). Infusion of norepinephrine, which caused a greater increase in splenic arterial pressure than did nerve stimulation, resulted in no release of bretylium-^{3}H into the perfusate. Release of the labelled amine by nerve stimulation persisted even though splenic contraction was blocked by phenoxybenzamine.

In other experiments, two cats, weighing 2–4 kg, received 80 μc./kg bretylium-^{3}H (20 mc./mg) intramuscularly. 14 h later they were anaesthetized with 'Nembutal' (30 mg/kg intraperitoneally), a tracheotomy performed, and artificial respiration instituted using a Harvard respirator. The right sympathetic chain was isolated just above the clavicle and the chest opened. The right stellate ganglion, upper thoracic sympathetic ganglia, cardiac nerves and heart were removed *en bloc*. The heart was perfused by the Langendorff technique with Krebs–Henseleit solution saturated with 95 per cent oxygen–5 per cent carbon dioxide and containing 1 g glucose/l. To ensure adequate drainage, both ventricles were vented with stab wounds. Cardiac rate and left ventricular contractile force were recorded on a Grass 5-*D* polygraph, with *FT*-03*B* force transducer. The stellate ganglion was stimulated with rectangular impulses of supramaximal voltage, 1-msec duration, using a Grass model 4 stimulator. Ten minutes after the start of perfusion, the preparation

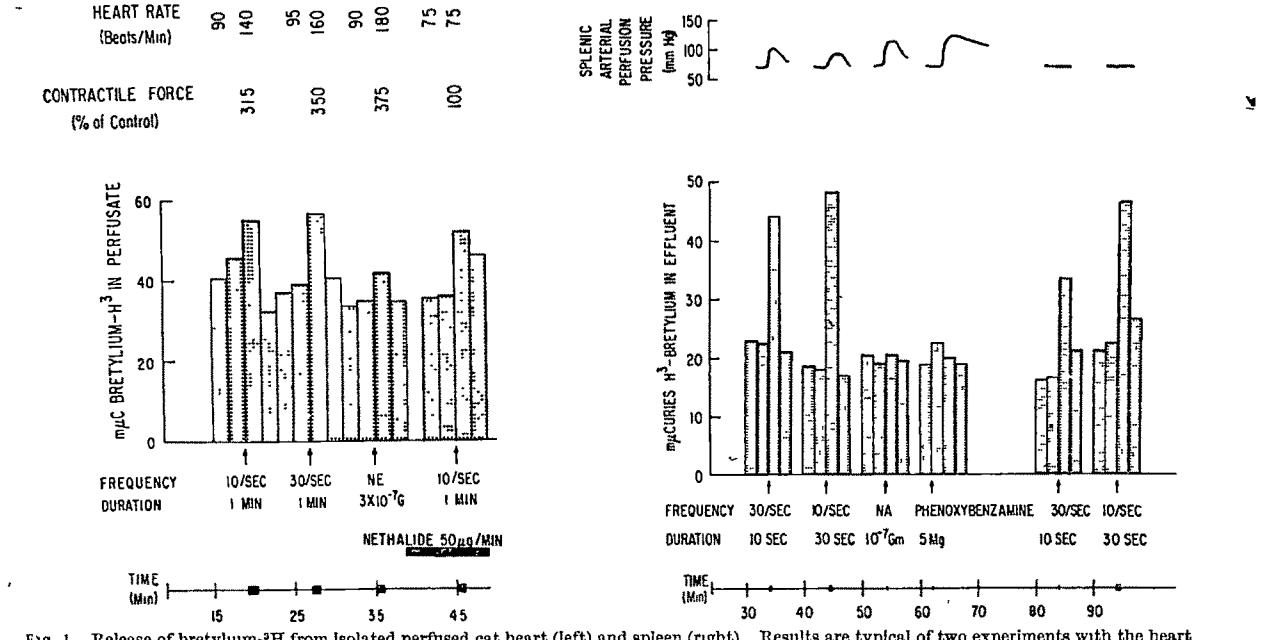

Fig. 1 Release of bretylium-^{3}H from isolated perfused cat heart (left) and spleen (right). Results are typical of two experiments with the heart and eight with the spleen

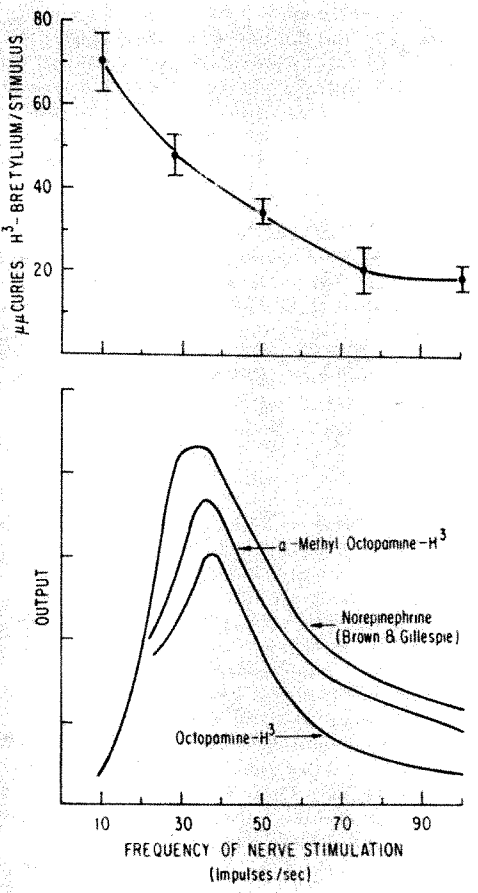

Fig. 2. Output of bretylium-^{3}H (top) at various frequencies of splenic nerve stimulation is compared with curves obtained for norepinephrine and other adrenergic false transmitters previously investigated

was tested by stimulating with 150 impulses during a 15-sec interval. Five minutes later, collection of the perfusate during 2-min consecutive intervals was begun. After two control periods, the ganglion was twice stimulated for 1 min at a frequency of 10 or 30 i.p.s. Norepinephrine 3×10^{-7} g was infused into the aortic cannula 8 min later. Stimulation was repeated during an infusion of nethalide (50 μg/min).

The effluent perfusate was centrifuged to sediment any red blood cells and bretylium was absorbed on 'Dowex 50' (NH_4^+) at 6·5 *p*H, and afterwards eluted with 6 ml. 3 N hydrogen chloride in ethanol. A portion of the eluate was assayed in a liquid scintillation spectrometer.

During sympathetic nerve stimulation an increased amount of bretylium-^{3}H was released from the isolated perfused cat heart (Fig. 1). A marked increase in cardiac rate and contractile force was noted during nerve stimulation (Fig. 1). Norepinephrine, which caused a similar increase in cardiac rate and contractile force, failed to release bretylium-^{3}H. When the inotropic and chronotropic effects of sympathetic nerve stimulation were blocked by the infusion of nethalide, a potent adrenergic-β-blocking agent, bretylium-^{3}H was still released by nerve stimulation. The spontaneous release of bretylium-^{3}H was unaltered by the adrenolytic drug.

The relationship of frequency of nerve stimulation to release of bretylium is shown in Fig. 2. The output of the labelled amine at stimulus rates of 10 i.p.s. is greater than that at 30 i.p.s. Phenoxybenzamine failed to elevate the rate of spontaneous release of bretylium (Fig. 1). Adrenergic blocking agents increase the resting output of norepinephrine[10] and false transmitters in heart[11] and spleen[6]. Furthermore, maximal release of norepinephrine[10] and false transmitters[6] is seen at frequencies of about 30 i.p.s. (Fig. 2). Bretylium does not behave in this manner (Figs. 1 and 2). Neither nethalide nor phenoxybenzamine elevated bretylium-^{3}H output at low frequencies of nerve stimulation. While norepinephrine and other typical adrenergic transmitters are released by acetylcholine, as well as by nerve stimulation, bretylium-^{3}H is not released by acetylcholine[11]. Bretylium is not a typical adrenergic false neurochemical transmitter, and probably does not replace norepinephrine. These findings suggest that bretylium acts at a stage between the nerve impulse and release of the adrenergic transmitter, possibly replacing an intermediate substance necessary for norepinephrine release.

In vitro MALIGNANT TRANSFORMATION OF CELLS BY FRIEND VIRUS

By T. OSATO, Prof. E. A. MIRAND, J. T. GRACE, jun., and F. PRICE

Roswell Park Memorial Institute, New York State Department of Health, and State University of New York at Buffalo, Buffalo, New York

PROPAGATION of Friend virus in mouse embryo cell culture was previously demonstrated in this laboratory[1,2].

This article concerns cellular morphological changes associated with the neoplastic property induced in early passages of the virus-infected mouse embryo cells and general characteristics of the resulting transformed cell line which has been maintained in this laboratory for 18 months.

The Friend virus used in this work was originally obtained from Dr. Charlotte Friend and was in its 48th serial passage in *HA/ICR* Swiss mice in this laboratory[3]. The titre of a 10 per cent infected spleen filtrate was approximately $10^{4.6}$ $I.D._{50}$/ml. when inoculated intraperitoneally into mice. This inoculum was free of polyoma virus so far as the incidence of multiple tumours and the antibody response against polyoma virus in injected mice were tested.

The test animals were *HA/ICR* Swiss new-born, 5–6-day-old suckling and 4–6-week-old mice obtained from the Roswell Park Memorial Institute breeding colonies.

The cell cultures used for inoculating Friend virus were primary cultures of *HA/ICR* Swiss mouse embryo tissues. Eight-ounce bottle cultures were prepared using Eagle's medium containing 10 per cent heat-inactivated calf serum as growth medium. Eagle's medium with 2·5 per cent heat-inactivated horse serum was used as the maintenance medium. These media were also used for

serial subcultivation of the virus-infected cells during the first 9 months, then substituted by Eagle's medium containing 10 per cent heat-inactivated foetal calf serum. Coverslip cultures were prepared in Leighton tubes for immunofluorescent staining and Wright–Giemsa staining. The indirect staining method was used in the immunofluorescent investigations[1,2].

Cell suspensions and cell-free supernates were injected intraperitoneally into mice to test leukaemogenic activity. Approximately 5×10^5 trypsinized cell suspensions were injected intraperitoneally or subcutaneously into suckling and young Swiss mice. Culture media were centrifuged and the supernates were injected intraperitoneally into new-born and young mice. To test intracellular leukaemogenic activity, cells were trypsinized and resuspended in small amounts of maintenance medium. They were disrupted by homogenizing and by freezing and thawing. After centrifugation the supernates were injected intraperitoneally into new-born and young mice. Criteria of Friend disease were based on splenic enlargement and histological and haematological examinations of the test mice.

To test the neoplastic property of the transformed cells, 1×10^5–5×10^5 cells were injected into new-born Swiss mice intraperitoneally or subcutaneously in the back.

For pathological investigations, specimens were fixed in 10 per cent formalin and stained with haematoxylin and eosin.

Three monolayer bottle cultures were inoculated with a 10 per cent infected spleen-cell-free filtrate and incubated 37° C for 3 h. The cells were then washed three times with Eagle's medium and held in a stationary position at 37° C following addition of maintenance medium. As controls, two out of eight bottles were inoculated with normal spleen filtrate, two with heat-inactivated infected spleen filtrate, two with neutralized infected spleen filtrate and the two remaining were not inoculated. Medium change was carried out every other day. After 25 days of incubation, each culture was transferred to two bottles using 0·2 per cent trypsin. Succeeding several transfers were then carried out every 4–10 days.

When leukaemogenic activity of the culture fluids of the virus-infected cells was tested on the sixteenth day, fifteen of sixteen mice (93·7 per cent) showed massive spleen involvement and polycythaemia, that is, typical Friend disease. Approximately 40 per cent of monolayer cells of the infected coverslip cultures were stained specifically by immunofluorescent staining.

More fluorescent cells were observed after transfer of the virus-infected cultures. When cell-grown coverslips were tested at the third passage, most cells were strongly fluorescent. The growth rate of these infected cells was considerably higher than that of controls.

In the fourth to sixth passages, after 1·5–2 months of the virus inoculation, proliferative foci of epithelioid cells with multi-nucleated giant cells were noted among fibroblastic monolayers. There was a tendency for the epithelioid cells to grow on top of one another, forming whitish and thickened plaques which were macroscopically visible. In the proliferative foci, only occasional fluorescence was observed in multi-nucleated giant cells. No significant degenerating process was observed in connexion with the appearance of the proliferative foci. These foci rapidly took the place of fibroblastic monolayers in two to three transfers. In the seventh passage, in which transformed foci were frequently observed, leukaemogenic activity of culture fluids was very weak. Only three of sixteen mice (18·7 per cent) showed splenic enlargement. In the eighth passage, there was no more leukaemogenic activity in cultured fluids. These cultures have been serially transferred once a week. This line (*TSME*-1) is at present in its 77th passage. The cell type is still epithelioid, but spindle-shaped cells are also present. Multi-nucleated giant cells are frequently observed at each passage-level. Confluent sheets are rapidly obtained with a tendency to overgrow one another, forming multi-layered areas. Rapid acidification of the culture medium is also noted. Control cultures were treated in the same way as infected cultures; however, all cultures degenerated after a few serial transfers. Fig. 1 shows 57th-passage *TSME*-1 cells in comparison with normal secondary mouse embryo cells. Epithelioid cells are predominant, but spindle-shaped cells are also present. Many multi-nucleated giant cells are observed. The nuclei are pleomorphic and the nuclear/cytoplasmic ratio is increased. Nucleoli increase in size and number and show a rounded outline. In contrast to the transformed cells, the cell type of normal mouse embryo cultures is primarily fibroblastic.

There have been no significant intracellular and extracellular leukaemogenic activities and no significant amount of Friend viral antigen in *TSME*-1 cell cultures since the transformed cell line was established. None of the 390 (0 per cent) injected with culture fluids and only 3 of 214 mice (1·4 per cent) injected with supernates after disrupting cells showed splenic enlargement. However, by injecting cell suspensions, 48 of 210 mice (22·9 per cent) have shown massive splenic enlargement although only occasional fluorescence has been observed in transformed cell culture by immunofluorescent staining.

To test the neoplastic property of the transformed cells, approximately 5×10^5 cells at the tenth passage were first inoculated into the subcutaneous tissue of the back of eleven new-born and intraperitoneally into twelve new-born Swiss mice respectively. By the ninetieth day, tumours developed in three of eleven (27·3 per cent) and in ten of twelve (83·3 per cent) respectively, and were first evident at 3–4 weeks. There was essentially no difference in growth characteristics between tumours induced with cells of different passage levels. In the latest experiment, approximately 5×10^5 *TSME*-1 cells in the 61st passage

(*A*) Control cells, primarily fibroblastic in morphology; (*B*) transformed culture, *TSME*-1. Note epithelioid morphology, multi-nucleated giant cells, and spindle-shaped cells

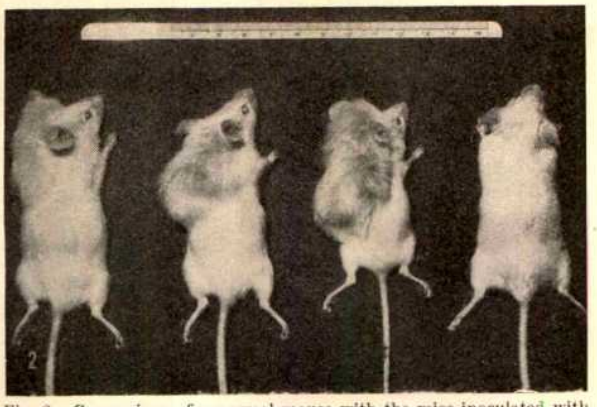

Fig. 2. Comparison of a normal mouse with the mice inoculated with sixty-first passage *TSME*-1 cells subcutaneously in the scapular region 30 days ago when new-born. Note big tumours in the back of 3 mice

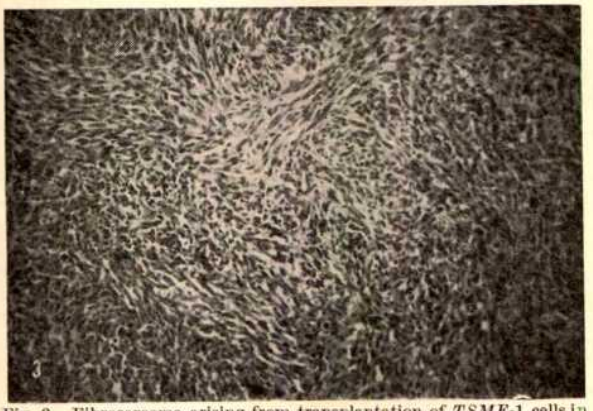

Fig. 3. Fibrosarcoma arising from transplantation of *TSME*-1 cells in the sixty-first passage. Haematoxylin and eosin stain. (× *c.* 50)

were inoculated into 89 new-born Swiss mice. By the sixtieth day, tumours developed in 14 of 44 mice (31·8 per cent) inoculated into the subcutaneous tissue of the back and 38 of 45 mice (84·4 per cent) inoculated intraperitoneally respectively, and were first evident at 1–2 weeks, attaining a diameter of 3–5 cm by the fourth–fifth week. They remained fairly localized. There was no gross evidence of metastasis. Fig. 2 shows a normal mouse and the mice which were inoculated subcutaneously in the scapular region with 5×10^5 cells at the 61st passage 30 days when new-born, followed by the development of large tumours. As illustrated in Fig. 3, these tumours are fibrosarcomatous. No tumours arose over a 5-month period of observation when 1×10^6–5×10^6 normal mouse embryo cells were inoculated subcutaneously or intraperitoneally into new-born mice. Also, no tumours arose by injecting Friend virus itself or cell-free materials of the transformed cultures into mice.

In the tumour-bearing mice, splenomegaly was frequently observed and large numbers of proliferating reticulum cells and erythroblasts were evident even in spleens which grossly were normal. High peripheral blood leucocyte counts with blast cells were usually found in the animals. Fig. 4 shows a normal mouse and the mouse which was inoculated intraperitoneally when new-born with 1×10^5 52nd passage *TSME*-1 cells at 60 days with the development of large abdominal tumours and an enlarged spleen. In contrast to the typical Friend disease, all the mice with leukaemia induced by inoculating the transformed cells were markedly anaemic regardless of the presence of tumours.

These findings indicate that Friend virus can induce a malignant transformation of normal cells *in vitro* as do certain oncogenic viruses[4]. In the transformed culture induced by RNA containing avian myeloblastosis virus, transformed cells were well differentiated and produced infectious virus progeny[5]. In the case of the RNA containing Rous sarcoma virus, transformed cells generally produce infectious virus progeny. Since the Rous sarcoma virus is defective, they totally fail to produce infectious virus under certain conditions. However, the presence of the viral RNA in the transformed cells can be demonstrated by infecting them with a related helper virus[6]. These transformed cells are characteristic of rounded or fusiform cells. Exceptionally, a transformation characteristic of polygonal cells with multi-nucleated giant cells has been reported[7].

In contrast to this, general characteristics of the Friend murine leukaemia virus-induced transformed culture resemble those of DNA containing SV_{40} (refs. 8 and 9). Friend virus proliferated continually in early passages of the virus-infected cells and rapidly became more difficult to detect in transformed cultures. Virus could only be recovered when transformed cells were inoculated directly into animals. There was loss of contact inhibition with a tendency for cells to 'pile up' in multiple layers. The cell type was epithelioid but spindle-shaped cells were also present. Multi-nucleated giant cells were frequently observed. Cultures acidified rapidly. An inverse relation between ease of viral propagation and ease of induction of cellular transformation *in vitro* was generally observed with polyoma virus and SV_{40} (refs. 10 and 11). However, it is characteristic of the system described here that transformed foci occurred rapidly in specifically fluorescent non-degenerating monolayers.

In the *TSME*-1 cell line, no significant amount of viral antigen and no significant intracellular and extracellular leukaemogenic activities have been detected; however, the results of the inoculation experiment of transformed cells may suggest that the cell line may be carrying the genetic information of Friend virus. Friend virus may be synthesized and released in a few cells among a large non-producing population, or the virus may be synthesized and released so slowly that it may be difficult to detect it by animal titration and immunofluorescent staining. It can also be assumed that the viral information can be carried as viral RNA in this transformed cell line. Such a small amount of virus or viral RNA in transformed cells will be activated by inoculating the cells into animals. Sufficient evidence to permit a conclusion is not available.

Friend disease induced by injecting the virus-infected tissue culture fluids into mice was characterized by a typical biphasic response—uncontrolled proliferation of reticulum cells followed by erythroblastosis and polycythaemia[12]. This was also the case with Friend disease induced in mice by injecting culture fluids in early passages of the virus-infected cells in which transformed cells were not yet observed. In contrast to this, mice with leukaemia induced by inoculating with transformed cells were markedly anaemic. This may suggest the presence of a variant of Friend virus in transformed cells. Previous work in this laboratory suggested that Friend disease may involve two agents—one responsible for the reticulum cell

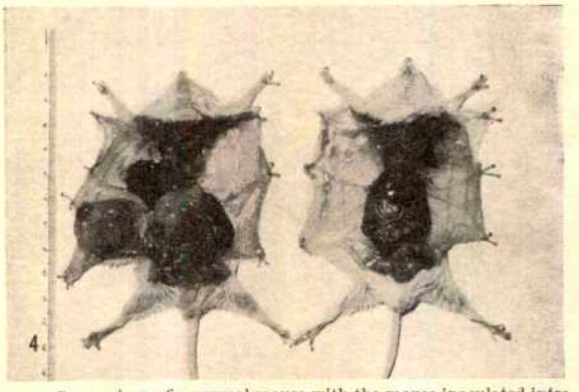

Fig. 4. Comparison of a normal mouse with the mouse inoculated intraperitoneally with fifty-second passage *TSME*-1 cells 60 days previously when new-born. Note big abdominal tumours and an enlarged spleen in the mouse on the left

SCIENCE COLLEGE.

disease and the other producing erythropoietic response (erythroblastosis and polycythaemia[13]). If this were the case, the former agent may be favourably selected in transformed cells.

Tumours arose after transplantation of cells at the tenth passage of the *TSME*-1 cell line at which transformation was established. This indicates a correlation of transformation by Friend virus *in vitro* with *in vivo* oncogenicity for the same species. The high tumour incidence (85–90 per cent) resulting from intraperitoneal transplantation of transformed cells into new-born *HA/ICR* Swiss mice is striking. Moreover, it has been consistently possible to re-isolate Friend virus from enlarged spleens of tumour-bearing mice. These splenic filtrates produced typical Friend disease but without polycythaemia.

Persistent infections of cells *in vitro* with murine leukaemia viruses were reported previously[14–16]. Manaker *et al.*[16] described tumour induction after transplantation of the Moloney virus-carrier cells into the isologous mouse strain. Since they used an established mouse spleen cell line to obtain the virus-carrier culture and since normal mouse cells carried in culture for long periods are known to undergo neoplastic change, they could not conclude that the virus was responsible for the induction of the neoplastic state. In contrast, data presented in this report support the idea that Friend virus can directly induce a neoplastic transformation of primary mouse embryo cells *in vitro*. Properties of the transformed cell line thus obtained have been stable for 1·5 years.

We thank Dr. Tetsuo Kimoto for his assistance. This investigation was supported in part by grants from the U.S. Public Health Service (*CA*–07745–02 and *AI*–04506–05) and the Hartford Foundation.

EFFECT OF DEOXYGUANOSINE ON SKELETAL DEVELOPMENT IN THE CHICK EMBRYO

By Prof. LOUIS J. PIERRO and JEAN SPIGGLE
Storrs Agricultural Experiment Station, University of Connecticut, Storrs

SEVERAL investigators have reported that deoxyguanosine can interfere with growth and development of the chick embryo[1–3]. Deoxyguanosine treatment of 4-day embryos resulted in rather severe stunting of growth, abnormalities of the eyes and facial skeleton, severe oedema, inhibition of feather development, and still other miscellaneous defects[1]. Under *in vitro* conditions, deoxyguanosine inhibited growth and development of the 11–13 somite chick embryo[2]. We have previously reported that as little as 25 μg deoxyguanosine is capable of interacting with actinomycin *D* in such a way as to increase the number of embryos which respond to the teratogenic action of the antibiotic[3]. Our continued investigation of the interaction in teratogenesis of the two compounds has of necessity included a detailed investigation of the effects of deoxyguanosine on skeletal development, the results of which are presented here. Apart from their potential significance for the elucidation of the interaction between deoxyguanosine and actinomycin *D*, the observations reported are of interest in that they illustrate that a measure of spurious regional specificity can be superimposed on the rather general inhibitory action of deoxyguanosine. Deoxyguanosine treatment of the chick embryo results in the death of large numbers of cells in a variety of tissues, including the brain and nerve cord, the scleratome and derma-myotome, the mesenchyme of the limb buds, the maxillary processes and visceral arches, the optic cup and head mesenchyme. However, readily predictable patterns of response can be elicited under appropriate conditions of timing and dosage. In one case, the induction of rumplessness, the response can be equated with the presence or absence of induced cell death in a spatially restricted region. The other response patterns elicited appear to be related to subsequent intra-organ developmental events, as yet undefined, which are precipitated by the widespread cell destruction.

In the experiments carried out, varying amounts of deoxyguanosine were injected into the yolk of fertile White Leghorn eggs which had been previously incubated for periods ranging from 0 to 120 h. Aqueous solutions were used, and the volume of fluid injected was never greater than 0·2 ml. After injection, eggs were re-incubated under standard conditions of temperature and humidity. Experiments were terminated at various stages, depending on their purpose. Dead embryos were detected by candling on the 6th, 9th and 13th days of incubation, unless experiments were terminated prior to these stages. Embryos dying before the 6th day were discarded; all embryos which survived beyond the 6th day were examined. In experiments which were terminated at the end of the 17th day of incubation, alizarin preparations of the surviving embryos were made in order to facilitate the detection of skeletal anomalies. As much as 50 μg of deoxyguanosine was found not to be teratogenic when injected into fertile eggs either prior to incubation or at 24 h. Data obtained from experiments in which embryos 48 h old or more were treated and allowed to develop until the 17th day have been summarized in Table 1.

48-h embryos. Injection of 50 μg of deoxyguanosine into the yolk sacs of 48-h embryos resulted in the death of approximately 50 per cent of the embryos before the 17th day of incubation. Most of the deaths occurred after the 6th day, and virtually every one of the dead embryos showed some axial defect. The most common defect involved a constriction of the trunk in the thoracic region with an accompanying malposition of the hind limbs.

Among the survivors of the 17th day of incubation, 30·7 per cent showed at least one defect, and most embryos were multiply affected. The most seriously defective embryos (3·8 per cent) were classified as phocomelic dwarfs. These embryos had extremely reduced limbs, facial coloboma and cleft palate, a shortening of either or both the upper beak or mandible, a shortening of the neck and trunk, and generalized oedema. Their tails

appeared to be normal, however. The remainder of the abnormal embryos were generally in the same size range as were control embryos and the treated embryos which appeared to be unaffected by deoxyguanosine treatment. Among these embryos defects involving the axial skeleton were approximately twice as prevalent as were facial defects and limb anomalies.

Axial defects observed among embryos treated at 48 h included a shortening of the neck and a shortening and constriction in the thoracic region. Examination of alizarin preparations of these abnormal embryos showed a reduction in the size but not in the number of cervical and/or thoracic vertebrae. The reduced vertebrae were compressed anteroposteriorly and partially fused. As might have been anticipated, rib anomalies were also seen in embryos showing abnormal thoracic vertebrae. Both types of axial defects were observed in the same embryo approximately as frequently as they were found separately.

Facial defects were found in 15·3 per cent of the embryos which survived the 17th day of incubation. These include facial coloboma, cleft palate and a reduction in either the upper or the lower beak. After treatment at 48 h, short upper beak was found in approximately three times as many embryos as was short lower beak. With rare exception, an embryo showing one of the facial defects also showed the other two.

In addition to the phocomelic embryos, some reduction in length of the wings and/or legs was seen in another 9·2 per cent of the survivors of the 17th day. Most of these micromelic embryos were affected bilaterally, but in a few cases only the limbs on the right side were affected.

Injections of 25 μg of deoxyguanosine were considerably less toxic to the 48-h-old chick embryo, and were also less teratogenic. The frequency of abnormal embryos was approximately one-half that observed after treatment with 50 μg; however, the incidence of axial defects was reduced by approximately two-thirds, and no phocomelic dwarfs were produced.

72-h embryos. Injections of 75–100 μg of deoxyguanosine approximated the LD_{50} dosage for embryos of 72-h incubation age. Again, most of the embryonic deaths occurred after the 6th day and abnormalities of the axial skeleton were found among the dead embryos. These included constrictions in the thoracic region, and also rumplessness. About 50 per cent of the embryos which survived the 17th day of incubation were abnormal, most being multiply affected. Phocomelic dwarfs similar to these encountered after treatment with 50 μg at 48 h accounted for approximately 5 per cent of the embryos. The remaining embryos showed defects of all the main skeletal regions.

Axial defects observed among survivors of the 17th day included short neck, reduced thorax and rumplessness. Short neck and rumplessness were each found in about 20 per cent of the embryos, and were frequently observed in the same embryo. Reduced thorax was found in less than 4 per cent of the embryos. As indicated in Table 1, facial defects were found in about 40 per cent of the embryos and micromelia in about 22 per cent. In some of the micromelic embryos, either only the limbs of the right side were affected, or the limbs of the right side were more drastically reduced than were those of the left side. A small number of embryos with foot defects were also observed.

In the group which had received only 50 μg of deoxyguanosine, 64·6 per cent of the embryos survived the 17th day and 17·7 per cent of these were abnormal. No phocomelic dwarfs were observed, and rumplessness was the only axial defect seen. The frequencies of axial, limb and foot defects were approximately one-half those found in the groups which had received 75–100 μg, whereas the frequency of facial defects was reduced by approximately three-fourths.

96-h embryos. Embryos of 96-h incubation age tolerated dosages of 100–200 μg of deoxyguanosine fairly well. Even in the 200 μg group, approximately 90 per cent of the embryos survived the 17th day of incubation, and only 3 per cent were phocomelic dwarfs. The frequency of abnormal embryos rose with increasing dosage from 22·4 per cent to 65·7 per cent and limb defects constituted the major class of abnormality. Axial defects, including rumplessness and short neck only, were obtained after treatment with 150–200 μg. Significant frequencies of facial defects were also found in these two experimental groups. A high incidence of foot defects was encountered for the first time. These included clubbing, microdactyly, ectrodactyly and syndactyly. In a number of embryos the feet were affected asymmetrically, but there did not seem to be any difference in susceptibility of right and left feet.

120-h embryos. Of 65 embryos of 120-h incubation age which had received 200 μg of deoxyguanosine, 60 survived the 17th day of incubation. Among these survivors, 63·3 per cent showed foot defects similar to those observed after treatment at 96 h, and 1·6 per cent had short mandibles. No other abnormalities were observed.

Axial Skeleton

When the particular axial defects produced were considered in relation to the time of treatment of the embryo, characteristic patterns of response were indicated (Table 2). Thoracic defects appeared to be characteristic of deoxyguanosine interference with axial development in 48-h embryos. Alternatively, rumplessness was a characteristic response of axial development when 72-h embryos were treated. On the other hand, cervical defects were fairly readily produced by deoxyguanosine treatment of either 48- or 72-h embryos.

An explanation for the pattern of response induced in axial tissues was sought in histological investigations of deoxyguanosine-treated embryos. Fertile eggs of 48- and 72-h incubation age were injected with 50 and 100 μg of deoxyguanosine, respectively, and re-incubated for periods of 1–7 days. Histological examination of embryos in both experimental groups which were killed 1 day after treatment showed clusters of degenerate cells in a variety of embryonic regions. Restricting attention

Table 1. Effects of Deoxyguanosine on Skeletal Development in the Chick Embryo
(Incubation Age and Dosage varied for White Leghorn Fowl)

Incubation age (h)	48		72			96			120

Foot defects	1·1	2·3	2·0	4·4	5·3	22·4	37·3	50·0	63·3

to axial structures, degenerate cells were abundant in the brain and nerve cord, and among the sclerotomal and derma-myotomal cells. They were not seen in the notochord, nor in the undifferentiated nodal mass and the unsegmented somite mesoderm. Examination of subsequent stages of development indicated that the axial defects were related to the destruction of cells in the nerve cord and in the scleratome. A description of the aberrant morphogenesis will not be presented here, but it is pertinent to note that in the defective regions the nerve cord was unable to elongate properly. For example, in the abnormally developing tail buds the nerve cord ended abruptly some distance anterior to the terminus of the notochord which was displaced dorsally until it virtually contacted the dorsal surface. Abnormal tail buds ceased to elongate and were afterwards resorbed, presumably due to the absence of a normal pattern of dorsal axial tissues[4]. In the thoracic and cervical regions, the failure of the nerve cord to increase in length was so marked in some embryos that the notochord which had increased in length so much more rapidly was folded back on itself. Presumably these embryos represented extreme cases and would have been among the early dead. It should also be noted that in all affected axial regions the pre-cartilaginous mesenchymal condensations were considerably reduced in size and cartilage formation was delayed by several days.

These investigations suggested a rather simple explanation for the failure of deoxyguanosine to induce rumplessness in 48-h embryos. No cell deaths were produced in the tail buds of 48-h embryos since the laying down of the nerve cord and the differentiation of the sclerotome and derma-myotome had not proceeded as far caudally as the tail bud by that stage. On the other hand, degenerate cells were present in the tail buds of embryos treated at 72 h, because by that stage the cells of the axial tissue had differentiated sufficiently to be sensitive to deoxyguanosine treatment. The explanation for the absence of thoracic defects in embryos treated at 72 h was not so obvious, however. Degenerate cells were found in the nerve cord and somite derivatives in embryos treated at 72 h. Quite possibly quantitative differences could have accounted for the different response of the thoracic regions of 48- and 72-h embryos, but cell counts were not attempted.

Facial Skeleton

An alternation of response was also suggested by the distribution of anomalies within the facial defect group. Short upper beak was a more frequent consequence of treatment of 48-h embryos than was short lower beak (10·5 and 2·9 per cent, respectively, after 50 μg; 5·0 and 0·0 per cent, respectively, after 25 μg). On the other hand, short lower beak was encountered more frequently than short upper beak after treatment of 72- or 96-h embryos (for example, 32·8 and 3·3 per cent, respectively, after 75 μg at 72 h; 19·2 and 1·1 per cent, respectively, after 150 μg at 96 h). As in the case of the differential response of the thoracic region, the explanation for this situation was not immediately apparent. Numerous degenerate cells were found in both the maxillary processes and the mandibular and other visceral arches after treatment at either the 48- or the 72-h stage. Again the need for quantitative studies was suggested, particularly since cell death has been implicated as a factor in normal development of the lower beak[5].

Limbs

According to the data presented in Table 1, the incidence of micromelia was approximately proportional to dosage at all stages from 48 to 96 h. Embryos were classified as micromelic whenever either the wings or the legs were shortened, however, and in fact it was only for the leg defect that this statement was true. The wings were shortened in the same percentage of embryos as were the legs after treatment at 48 h, but fewer embryos had shortened wings after treatment at 72 or 96 h. The susceptibility of the leg buds, on the other hand, appeared to remain fairly constant between 48 and 96 h, and even until 120 h, since the micromelic embryos were quantitatively replaced by embryos with foot defects after treatment at the latter state.

Although the susceptibility of the leg bud remained constant from 48 to 120 h, the response elicited by deoxyguanosine did show significant variation depending on the stage of the embryo at the time of treatment. The pattern observed was consistent with a distal shift with age of the region of maximal susceptibility to deoxyguanosine, except for some complication after treatment at 72 h. At all stages from 48 to 96 h, a number of treated embryos were found in which combinations of two or more long bones were reduced in length. These were most frequent after treatment with the higher dosages at each stage, and included the phocomelic embryos already described. In addition, embryos were found in which only one of the long bones of the leg was appreciably shortened. Thus, after treatment of 48-h embryos with 25–50 μg of deoxyguanosine the tibiotarsus alone was reduced in all sixteen micromelic survivors of the 17th day of incubation. Examination of alizarin preparations showed that the fibula was approximately normal size, although sometimes bent, in these embryos. After treatment of 96-h embryos, on the other hand, the tarsometatarsus bone alone was reduced in 92 out of 94 micromelic embryos. After treatment of 72-h embryos with 50 μg of deoxyguanosine in twelve out of thirteen micromelic embryos only two long bone rudiments were present, one of which was the tarsometatarsus. The fibula was missing, and either the femur was also missing, or the femoral and tibiotarsal rudiments had been so reduced that the two had undergone tandem fusion at some time during their development. In the groups of micromelic embryos produced by treatment with 75–100 μg of deoxyguanosine at 72 h, 26 of 37 embryos also had only two long bone rudiments present in at least one of their legs. Of the remaining eleven embryos, the tibiotarsus was reduced in four, the tarsometatarsus in one, and 6 were multiply affected. An apparently similar situation was observed in the reduced wings of some embryos; for example, the most proximal long bone appeared to be missing. In the wing, two adjacent bony rudiments of unequal size were found proximally. These could have resulted from a situation in which the femoral, ulnar and radial rudiments were all reduced, followed by tandem fusion of the femoral and ulnar rudiments. A possibly comparable situation has been described by others[6], but has been explained as being due to the absence of the humerus and marked reduction of the radius. This

Table 2 Distribution of Axial Defects in Deoxyguanosine-treated Chick Embryos (Incubation Age and Dosage varied for White Leghorn Fowl)

Incubation age (h)	48		72			96		
Dosage (μg)	25	50	50	75	100	100	150	200
Survivors of 17 days	175	130	113	91	75	58	110	98
Axial defects (%)	8 6	30 7	14·1	27·4	42·6	0 0	2 2	9 1
Short neck	6 8	26 8	0 0	22 2	20·4	0 0	2 2	5 1
Thoracic defect	6 8	24 8	0 0	0 0	3 8	0 0	1 1	3 0
Rumplessness	1 1	0 0	14 1	17 6	28 1	0 0	1 1	2 0

appears less likely as an explanation for the present results, but further investigations are needed.

In view of the availability of 'fate maps' for the various components of the developing limbs[7], investigations were undertaken in order to determine if distinctively located populations of deoxyguanosine-sensitive cells could be detected. Fertile eggs which had been incubated 48, 72, 96 or 120 h were injected with 50, 50, 100 and 200 μg of deoxyguanosine, respectively, and embryos were collected at various times after treatment. Live embryos were then vitally stained with Nile blue sulphate according to the procedure of Saunders *et al.*[8], and the location of degenerate cells in the leg buds noted. With only rare exceptions, embryos killed 24 h after treatment showed a fairly even distribution of degenerate cells throughout their leg bud mesenchyme. The response pattern then did not appear to be related to the spatial distribution of sensitive cells. Presumably it was determined by subsequent internal rearrangements possibly directed by factors such as the competitive interactions among the long bone rudiments which have been reported in recent years[9].

The investigations described here confirm and extend the earlier observations of Karnofsky and Lacon[1] regarding the teratogenic capability of deoxyguanosine. Failure to record such a capability in our previous investigation[3] can presumably be traced to a combination of factors such as duration of experiments, small dosage of deoxyguanosine and sampling error. Previous experiments were terminated at the end of 8 days, a time at which it is difficult to detect either the relatively slight effect of 25 μg of deoxyguanosine on thoracic development or even the eventually more marked shortening of the neck. The reasons why deoxyguanosine is cell toxic and consequently teratogenic are not known. That embryos can be protected against the effects of deoxyguanosine by supplementary treatment with cytidine has been reported by several investigators[2,10]. It has been suggested that deoxyguanosine inhibits the enzyme deoxycytidylate deaminase[2], and thereby interferes with DNA synthesis, but direct evidence for this inhibition is lacking. Deoxycytidylate deaminase has been shown to be inhibited in an *in vitro* test system by deoxyguanylic acid, however, and it is possible that deoxyguanosine becomes teratogenic only after phosphorylation *in vivo*[2]. We have found that the latter is not so effective a teratogen in our *in ovo* test system as is deoxyguanosine, but the possibility that permeability to the phosphorylated compound is reduced has yet to be examined.

PSILOCIN: EFFECTS ON BEHAVIOUR AND BRAIN SEROTONIN IN MICE

By Dr. ROBERT L. COLLINS, Dr. J. MARK ORDY and Dr. THADDEUS SAMORAJSKI
Department of Neurochemistry, Cleveland Psychiatric Institute, and School of Medicine, Western Reserve University, Cleveland, Ohio

PSILOCYBIN and psilocin have recently been included on the list of psycho-active agents. Psilocin, or dephosphorylated psilocybin, has been structurally identified as 4-hydroxy-*N* : *N*-dimethyltryptamine[1]. Clinical reports have indicated that the hallucinogenic effects of psilocin in man are quite similar to those of LSD-25, but of shorter duration[2], and that its distribution in the brain and other organs is more uniform[3]. Other findings have indicated that psilocin is an analogue of 5-hydroxytryptamine and possesses certain serotonin and anti-serotonin properties[4].

Although a number of investigations have reported behavioural differences in laboratory animals to experimental serotonin alteration[5,6], and others have indicated brain amine variations following administration of psychotomimetic compounds[7], few multidisciplinary investigations have attempted to relate changes in brain serotonin and behaviour following psychotropic drug treatment in a single experimental design.

The present experiments were conducted to determine specific directional behavioural changes in mice to psilocin administration, to correlate these changes to possible directional variations in total-brain serotonin, and to separate the effects of psilocin on serotonin-levels from possible non-pharmacological effects.

Groups of 20 adult female mice from the highly inbred *C57BL/10J* strain were used as subjects. All experimental mice were maintained under rigid laboratory conditions with free access to Purina mouse chow and water until 90 days of age. At the beginning of experiments, subjects were matched for age and weight and then randomly assigned to experimental groups. Groups designated '*A*' and '*B*' received 10 mg/kg psilocin or an equal volume of placebo, respectively. Psilocin was dissolved in dilute hydrochloric acid and administered orally by means of a beaded-tip syringe. On each of five successive test days, groups received psilocin or placebo 1 h before testing. To evaluate possible carry-over effects as well as changes in performance following psilocin withdrawal, both groups received oral placebo during five additional days of testing. Naive groups were used in each behavioural test.

Psilocin-induced changes in behaviour were evaluated in the following tests: (1) shock-elicited escape-avoidance conditioning; (2) open field exploration; (3) locomotor activity wheel running. Details concerning apparatus and procedure have previously been presented[8].

Serotonin content (5-hydroxytryptamine, 5-HT) in individual whole brains was determined by the spectrofluorometric technique of Bogdanski *et al.*[9]. To ensure that serotonin measurement would not be confounded with systematic differences in daily runs, 5-HT-levels were evaluated from randomized treatment group samples on an individual day. Concurrent daily standards were run, and all scores corrected for daily percentage recovery. Recovery ranged from 87 to 93 per cent. Psilocin was run under identical spectrofluorometric conditions but it could not be detected.

Serotonin content in individual whole brains was determined for six groups of mice. Groups 1 and 6 were identically matched non-handled controls; these mice were obtained directly from laboratory stock and immediately killed. Brains from Group 1 subjects were analysed concurrently with those of the treatment groups, while Group 6 was added at the completion of the analysis to

further verify serotonin-levels in non-handled mice. Group 2 received 50 mg/kg psilocin. Group 3 received an equal volume of HCl vehicle. Group 4, designated sham placebo, received experimental manipulation alone without oral administration of either drug or vehicle. Group 5 received 5 mg/kg reserpine. With the exception of non-handled mice, all treatment subjects were returned to individual cages for 1 h before being killed. A total of sixty whole brain serotonin determinations were made.

Analyses of variance were used to detect differences in behaviour, while an unweighted means analysis of variance was used to assess the serotonin data in which there were slightly unequal sub-class numbers[10]. In addition, an extension of the Newman–Keuls' multiple range test was used to perform all intergroup serotonin comparisons (carried out in pairs)[11]. Unless otherwise noted, degrees of freedom for F-ratios were 1/190.

Table 1. SUMMARY OF MEAN BEHAVIOURAL PERFORMANCE FOR GROUP *A* (10 MG/KG PSILOCIN) AND GROUP *B* (PLACEBO)*

	Open field exploration				Avoidance conditioning			
	Latency (sec)		Squares traversed		Latency (sec)		Avoidance number

4	2·62	2·26	38 9	59·2	2·53	2·27	12·9	13·7
5	2 39	2·21	59·3	79·5	2·22	1·90	14·7	15·3
Mean	2·66	2·30	47·7	63·2	3·29	2·94	8·6	9·4
Day 6	2·88	2·37	70·5	64·8	2·12	2·21	15·3	14·5
7	2·71	2·05	76 6	66 4	2·10	2·06	15·7	15·3
8	2·94	2 32	66 9	66·2	2·11	1·91	15·7	15·3
9	2·81	2·14	72·3	61·3	1·94	2 02	16·6	16·8
10	2·10	2·14	69 9	64·2	2·22	2·15	15·3	15·3
Mean	2·69	2 20	71·2	64·6	2 10	2·07	15·7	15·8

* Both groups received oral placebo during days 6–10.

Table 1 summarizes the mean performance scores for open field exploration and avoidance conditioning for psilocin and placebo groups. During the first 5 days, psilocin-treated mice explored less in an open field than placebo mice ($P < 0{\cdot}0001$; $F = 17{\cdot}4$). On days 6–10, during which all mice received oral placebo, the exploration mean of Group *A* was higher than Group *B*. This reversal suggested that cessation of psilocin facilitated exploration performance. However, the statistical analysis did not reject the null hypothesis that this shift was a chance event ($P \simeq 0{\cdot}08$; $F = 3{\cdot}15$). Psilocin mice exhibited longer latencies to move from the middle square during the first week ($P < 0{\cdot}025$; $F = 5{\cdot}83$), as well as during the second week ($P < 0{\cdot}005$; $F = 9{\cdot}01$). Thus, the effect of psilocin on open field latencies persisted beyond drug withdrawal.

Both groups learned to avoid shock to an asymptotic level by 5 days of testing. However, mice which received psilocin traversed the runway more slowly ($P < 0{\cdot}001$; $F = 12{\cdot}6$). This 0·35 sec mean decrement was relatively constant during the 5 days of psilocin administration. During days 6–10, Group *A* performance did not differ from that of Group *B* ($P > 0{\cdot}5$; $F = 0{\cdot}3$). To distinguish whether the increased latency of psilocin-treated mice during the first week reflected a learning deficit or decreased locomotor ability, the mean number of avoidances per session were analysed for both groups. During the first 5-day period, Group *A* averaged 8·64 avoidances and Group *B* 9·44 avoidances. The difference between these averages was not significant ($P > 0{\cdot}25$; $F = 1{\cdot}17$). During the final 5-day period, the averages for Groups *A* and *B* were 15·7 and 15·8 avoidances, respectively. Whereas the analyses indicate that psilocin resulted in a decreased ability to traverse the runway, they did not indicate a differential effect on avoidance acquisition.

To evaluate the effect of psilocin and reserpine on spontaneous activity, four groups of mice were pretrained in activity wheels until a stable performance of 4,000 rev per 2 h period was attained. On each of five successive test days, treatment groups received oral administration of 50 mg/kg psilocin, 10 mg/kg psilocin, 5 mg/kg reserpine, or placebo 1 h before testing. Fig. 1 illustrates the group mean locomotor performance during five test days.

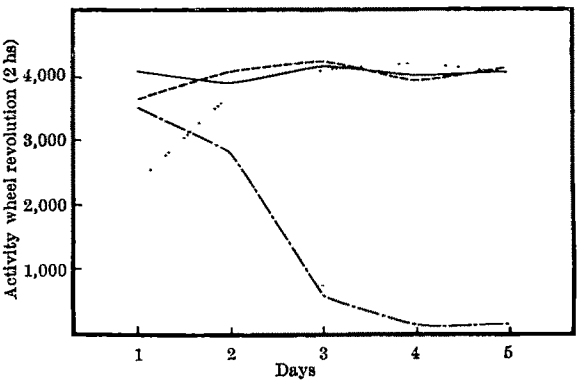

Fig. 1 Daily performance averages of spontaneous locomotor activity for four groups of mice administered psilocin, reserpine, or placebo. ———, placebo; – – –, psilocin, 10 mg/kg; ·····, psilocin, 50 mg/kg; – – –·–, reserpine, 5 mg/kg

Data analyses by simple-effects analyses of variance and multiple range tests indicated that the day 1 locomotor performance of both psilocin groups was significantly lower than placebo scores ($P < 0{\cdot}0001$; $F = 35{\cdot}3$, d.f. = 2/285). By the second day, groups which received psilocin regained asymptotic levels and did not differ from the control group ($0{\cdot}25 < P < 0{\cdot}5$; $F = 1{\cdot}02$, d.f. = 2/285). By contrast, the reserpine-treated group did not differ from controls on the first day of testing, but differed from the control group as well as psilocin-treated mice, beginning on the second day ($P < 0{\cdot}001$; $F = 11{\cdot}8$, d.f. = 3/380). These data indicate that psilocin administration produced decrements in locomotor performance on the initial treatment day, that the degree of decrement was a function of the dosage, and that psilocin had no effect on wheel running from the second day onward.

The results of the sixty serotonin determinations are summarized in Table 2. An unweighted means analysis of variance demonstrated highly significant differences in whole brain serotonin levels among the six groups ($P < 0{\cdot}0001$; $F = 46{\cdot}2$, d.f. = 5/54). Application of the Kramer–Newman–Keuls' multiple range test demonstrated that the mean serotonin-levels fell into three non-overlapping major groupings ($P < 0{\cdot}01$). Groups 4, 3, and 2 did not differ among themselves, but differed from all remaining groups. Both groups of non-handled controls did not differ between themselves, but differed from all other groups. In addition, the group which received reserpine differed from all other groups. The mean serotonin-level of the psilocin group did not differ from either the HCl or sham-placebo groups. By contrast, the serotonin content in both groups of non-handled controls was 11 per cent lower than sham-placebo, HCl, and psilocin scores. The analyses suggest that experimental handling alone may have been responsible for the significant elevation of 5-HT for Groups 4, 3, and 2, since one treatment condition common to these groups was experimental manipulation. The highly significant depletion of serotonin in Group 5 which received reserpine is consistent with many previous findings[12].

Some recent evidence has suggested that central nervous system amines are responsive not only to pharmacological alteration, but also to environmental stressors requiring extensive adaptation. Whereas Barchas and Freedman[13] reported an average 13 per cent increase in whole brain serotonin in rats exposed to prolonged forced activity or a 15 min cold swim, the present findings demonstrate that

Table 2. MEAN WHOLE BRAIN SEROTONIN-LEVELS (μG 5-HT/G WET TISSUE)

Treatment	Sham placebo	HCl vehicle	Psilocin (50 mg/kg)	Non-handled controls		Reserpine (5 mg/kg)
Group number	4	3	2	1	6	5
No. of subjects	10	10	9	11	11	9
5-Hydroxytryptamine	1·27	1 21	1·21	1·12	1·05	0·90

Group means underscored by a common line do not differ statistically among themselves, but differ significantly from remaining groups ($P < 0{\cdot}01$). Average standard error for treatment means equals 0 022 μg 5-HT/g wet tissue.

a comparable elevation in brain serotonin may result from relatively mild handling stress in mice. Since these results indicate that total brain serotonin content may be confounded with levels of adaptation or arousal, future pharmacological investigations which utilize neurohumour levels as dependent variables should incorporate adequate control procedures to separate possible treatment differences from placebo effects.

The behavioural findings observed in this investigation indicate that psilocin produced consistent decrements in open field exploration parameters and avoidance conditioning running, but did not appreciably influence avoidance acquisition. The data suggest that open field exploration was enhanced following psilocin withdrawal, and that latency decrements persisted. In addition, psilocin treatment was associated with a dose-dependent decrement in spontaneous locomotor activity on the initial day of treatment, with rapid tolerance development by day 2.

The comparison of the biochemical and behavioural findings is noteworthy in several respects. For example, the significant decrease in day 1 activity wheel performance of both psilocin-treated groups was not associated with a corresponding variation in endogenous whole brain serotonin. Thus, psilocin significantly altered behavioural performance without altering serotonin-levels. Conversely, the locomotor performance of mice administered reserpine did not differ from placebo mice on the first day of testing, although brain serotonin-levels were depleted 29 per cent. Thus, a dramatic change in brain serotonin-level was not associated with a concurrent alteration in behaviour. These results indicate a lack of correlated response between brain serotonin content and certain behavioural criteria.

EVOKED POTENTIALS CORRELATED WITH A VISUAL ANOMALY

By Prof. D. M. MacKAY and Dr. ADRIANA FIORENTINI
Department of Communication, University of Keele, Staffordshire, and Institute of Optics, Florence, Italy

An incoherent succession of randomly patterned optical images ('dynamic visual noise') offers a useful stimulus to probe the visual system and reveal any bias present in perceptual mechanisms[1–3]. The present investigation concerns the physiological correlates of a curious visual anomaly discovered some years ago when using a stimulus of this kind[4]. If each frame of such a visual noise sequence is followed by a short bright flash of light in the same eye, illuminating the same area of the visual field, then with a certain critical time interval between frame and flash, and at frame repetition rates of the order of 5–20 per sec, the random 'Brownian movement' normally perceived in the visual noise field is disrupted. In its place (or in addition), the screen appears to be filled with elongated objects resembling maggots, which seem to wriggle to and fro at random and link up to form long chains or chain-mesh patterns. The critical lag between the onset of each noise frame and the blank flash varies with frame duration, repetition frequency and intensity[5], but is typically of the order of 18–25 msec.

This is not the only visual anomaly that may be observed with such interlaced sequences of stimuli. With a somewhat longer time interval between frame and flash, Dr. J. P. Wilson[6] has reported that spurious impressions of contour motion are produced with stationary stimulus figures. A stationary black disk on a stroboscopically-illuminated white ground, for example, may appear to be continually expanding or contracting according to the time interval between the illuminating flashes and the blank flashes[6]. (Explanations in terms of eye movements are ruled out, for with a more complex field such as a black annulus one may see simultaneously a contraction of the inner edge and expansion of the outer.)

On both scores it seemed worth while to ask whether the occipital evoked potentials, as recorded from scalp electrodes, showed any corresponding anomalies at the inter-stimulus intervals giving rise to these phenomena. The preliminary investigation to be reported here indicates that they do, and appears to give evidence of a specific sensitivity, at the critical phase, to the presence of spatial patterning in the visual stimulus.

In place of the cine projector used in the earlier investigations[4,5] a high-powered electronic stroboscope was used to illuminate an area of 'static visual noise'—an enlarged photograph of sand paper, mounted on a turntable, and viewed through a circular (non-concentric) aperture. The turntable could be rotated asynchronously, so as to present a substantially unrelated sequence of visual noise samples when required[2]. A second stroboscope illuminated a plain white disk of the same size as the exposed area of visual noise, the two being optically superimposed by means of a half-silvered mirror. These fields subtended an angle of about 10° at the observer's eye. The repetition period and relative timing of the two stroboscopes were adjustable in steps of one msec.

Scalp electrodes were positioned as shown in Fig. 1, with the reference electrode 2 cm above the inion and inter-electrode distances of 5 cm, so that longitudinal (*A*) and transverse (*B*) components of the electric field could be simultaneously recorded and compared. Conventional electronic computing equipment (a Mnemotron '*CAT*'), triggered synchronously with the visual noise exposure, enabled the two evoked components *A* and *B* to be averaged on separate channels; a typical run lasted for 1 min and represented the sum of 500–1,000 responses.

To summarize the results (to be presented more fully elsewhere), the critical phase of our double-flash stimulation was indeed found to be accompanied by anomalies in the evoked potential. A sample run with a repetition period of 63 msec is shown in Fig. 1, where the number on the left of each pair of tracings represents the lag in msec between noise and blank flashes, and that on the right shows the order in which runs were made (subject A. F.). Since the perceptual anomalies in question are visible only at repetition rates above 5 or 6 per sec, their corresponding evoked potentials have a large continuous and oscillatory component, and the waveforms shown represent one complete cycle of a repetitive train. Slow changes in

form occur even under steady conditions, but in view of the order in which runs were made the general trend emerges clearly in Fig. 1. With a cycle period of 63 msec, the most striking change may be seen to occur in the transverse (*B*) component at values of lag between 13 and 23 msec, where the amplitude grows markedly and the phase also changes more rapidly than elsewhere. Striking also is the change in relationship between the longitudinal and transverse components, reflecting as it does a shift from virtual synchrony into near antiphase, and the appearance of a marked third harmonic in the longitudinal component. The psychophysically observed delay range for the 'maggot' effect in this case was 15–24 msec, with an optimum at 18 m.sec.

In order to disentangle the factors that might be responsible for the electrophysiological anomaly, a series of further experiments were performed. First, the rotating noise field was brought to rest, so that successive noise frames were identical. Subjectively, the effect at the critical phase was to replace the 'maggots' by a (much fainter) impression of a pulsating lace-work structure in the static noise pattern. The corresponding evoked potentials, however, showed remarkably little difference from those of Fig. 1, apart from a suggestion of an increased lag in the longitudinal component at the critical interval of 18 m.sec.

This raised the question whether the anomalies in the evoked potentials were related at all to spatial patterning in the stimulus, or whether only the temporal rhythm of the light entering the eye was responsible. Accordingly, the responses with the visual 'noise' pattern were compared with those obtained with a uniform grey surface of comparable overall reflectance, under two conditions: (1) blank flash following each frame at the critical interval for the 'maggot' effect; (2) blank flash preceding each frame by the same interval.

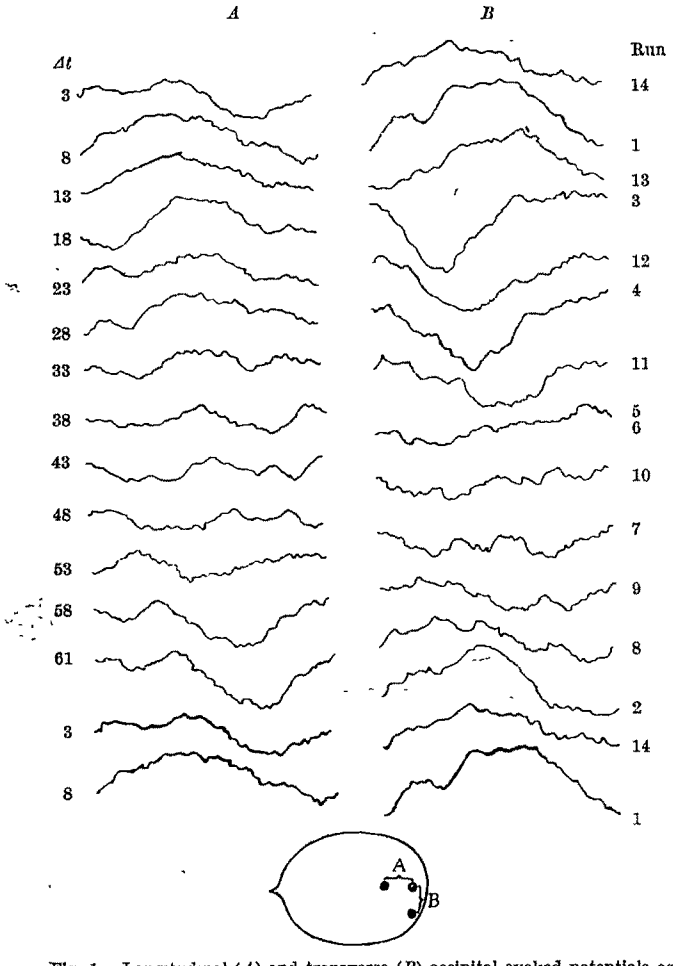

Fig. 1. Longitudinal (*A*) and transverse (*B*) occipital evoked potentials as a function of interval Δt between noise frame and blank flash. Intervals are shown on left; run numbers on right. Electrode placements were as indicated, with bipolar connexions. Period of stimulus cycle 63 msec

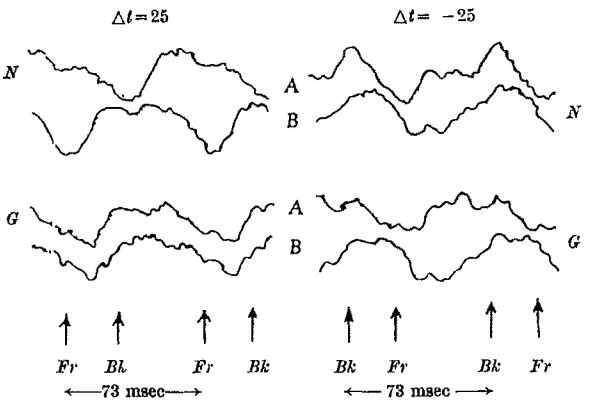

Fig 2. Effects of stimulus patterning on evoked potentials for $\Delta t = +25$ ('critical interval') and -25 msec. *N*, With noise field; *G*, with uniform grey field. Note that almost two complete cycles are shown, with a cycle period of 73 msec

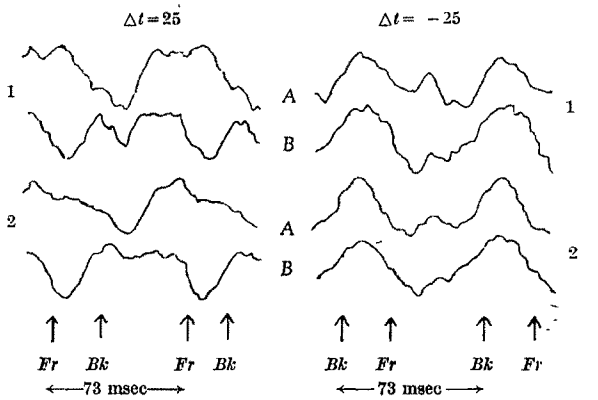

Fig 3. Control runs showing effects of intensity change on evoked potentials. Intensity for run (1) was greater by 0·5 log unit than for run (2)

The results with a repetition period of 73 msec, for which the critical interval (Δt) was 25 msec, are shown in Fig. 2, where the longitudinal (*A*) and transverse (*B*) response components in each case are presented one above the other. It will be seen that under the critical condition for the 'maggot' effect ($\Delta t = 25$) the change from noise (*N*) to uniform grey (*G*) made a marked difference to the phase relationship between the longitudinal and transverse components; but that when the blank flash (*Bk*) preceded the frame (*Fr*) by the same time interval ($\Delta t = -25$), the same change from noise to grey had a much smaller effect.

Though care had been taken to match the overall subjective brightnesses of noise and grey fields, the possibility that a brightness difference was responsible for the contrast in evoked potentials was checked by performing two runs with the same noise frame, but at frame brightness levels differing by approximately half a log unit. As will be seen from Fig. 3, the effects of this (subjectively large) change in brightness were both smaller than, and quite different from, those produced by the change from noise to patternless stimulation at subjectively constant brightness. It seems fair, therefore, to conclude that at the critical phase the evoked potentials show an enhanced response to the introduction of patterning as such into the visual field, and that this response takes the form of a change in the relative phase of longitudinal and transverse evoked potentials. Further work is needed, however, with more subjects, to test the generality of this conclusion.

It seems clear from these observations that stimulation of the visual system in specific uneven temporal rhythms calls out anomalous neural responses which are reflected

physiologically in a change of spatial and temporal activity patterns at the cortical level, and perceptually in the imposition of spurious structure on an otherwise incoherent visual field. Unlike the well-known 'stroboscopic patterns'[7] evoked by regularly repetitive flashes, which are most noticeable against a blank background, these perceptual effects are seen most clearly when optical contours are present in at least the first of each pair of stimuli. In this respect they resemble the familiar after-effect of visual image motion, which may be interpreted as due to the activity of a sub-system responsible for signalling motion-as-such, the output of which is perceptually 'attributed' to whatever structure is present in the visual field. In the absence of a structured stimulus the effect has only the residual entoptic irregularities on which to manifest itself.

The suggestion here would be that the spurious contours imposed on incoherent stimuli at the critical phase may result from the excitation of a sub-system the elements of which are normally set to detect local contours in the retinal image[8], but at the critical phase (as the result of a kind of resonant response to the rhythm of the stimulus) become abnormally excitable. A similar temporal rhythm-sensitivity in the motion-detecting sub-system could account for Wilson's effect[6].

The results shown in Figs. 2 and 3, though far from conclusive, seem to be in line with this suggestion, since they indicate that a major change in the sensitivity of cortical activity to temporal rhythm in the stimulus occurs when a spatially patterned stimulus is substituted for a patternless one of similar overall luminance. The fact that no similar effects are observed when the frame and flash are presented to different eyes would suggest that the mechanisms involved are fairly near the periphery of the visual system.

ACTIVE TRANSPORT OF GLUCOSE BY SUSPENSIONS OF ISOLATED RAT INTESTINAL EPITHELIAL CELLS

By Dr. BABETTE K. STERN
Gastroenterology Section, Department of Medicine, and Department of Biochemistry, University of Chicago
AND
Dr. WESLEY E. JENSEN*
Gastroenterology Section, Department of Medicine, University of Chicago

THIS article presents data on the active transport of glucose into the isolated, intact, functioning rat intestinal epithelial cell. Much of our knowledge of the mechanism of amino-acid and sugar transport in the intestine has been derived from observations with various types of *in vivo* and *in vitro* intestinal preparations[1,2]. The use of suspensions of isolated intestinal epithelial cells prepared by the method developed by Harrer, Stern and Reilly[3] affords an advantage over other preparations in that they are uncontaminated by mesenchymal elements and are free of the normal homoeostatic mechanisms that operate when the cells are organized into a tissue. Huang[4] recently reported on the energy-dependent uptake of L-tyrosine and 3-*O*-methyl glucose by intestinal epithelial cell suspensions from the rabbit. Our method appeared to produce much purer cell preparations than did that used by Huang, as his cells were obtained after chopping up the entire intestine, incubating with lysozyme, filtering through gauze and washing. It is likely that his cell preparations were contaminated with other types of cells and debris. With the method we used, only cells from the lumen of the intestine were obtained, and careful microscopic examination revealed that the basement membrane of the intestine was intact.

Suspensions of rat intestinal epithelial cells were prepared as described by Harrer, Stern and Reilly[3] and Stern and Reilly[5] with the following modifications: citrate was used to dissociate the epithelial cells from the mucosa. The composition of the medium was: 0·096 M sodium chloride, 0·008 M potassium phosphate, 0·027 M sodium citrate, 0·0056 M dibasic sodium phosphate, 0·0015 M potassium chloride—final *p*H 7·2. 15,000 U. of penicillin and streptomycin were added per 100 ml. of all solutions used. The lumen of the small intestine was filled with this solution and incubated for 11 min at 33° C. All subsequent operations were carried out at 0°–4° C unless otherwise indicated. This solution was removed following the incubation and either a solution composed of 0·137 M sodium chloride, 0·0115 M potassium phosphate, 0·008 M dibasic sodium phosphate, 0·0022 M potassium chloride—final *p*H 7·2, or 0·2 M sucrose, 0·05 M sodium potassium phosphate, *p*H 7·4 (sodium ion = 0·076 M potassium ion = 0·019 M), was washed through the lumen of the intestine. The cells were released from the mucosa by gently pressing the filled intestine with one's fingers. The cells were suspended in 40 ml. of either the inorganic salt solution or the sucrose phosphate solution and centrifuged at 500*g* for 10 min. 0·4–0·8 ml. of packed cells were suspended in 7·7 ml. of one or other of the foregoing media. To this suspension was added 30 μg of crystalline DNase (Nutritional Biochemical Corp.), 0·07 ml. of 0·25 M D-mannitol-1-^{14}C, 0·02 ml. of 0·4 M $MgSO_4$ to a final volume of 7·82 ml. D-Mannitol-1-^{14}C was used to measure extracellular space since it is not absorbed by the intestine[6]. DNase was added to reduce the viscosity of the reaction mixture. Bare nuclei, and some lysed cells and mucus contributed to the relatively high viscosity. The initial glucose content of the cells, as determined on a portion of the reaction mixture, was negligible. The reaction mixture was transferred to a Warburg flask for the incubation. When glucose uptake was measured in the balanced salt solution, 0·11 ml. of 0·0762 M glucose was added from the side arm. When 4,6-dinitro-*o*-cresol was present, the reaction mixture was pre-incubated for 5 min under argon before the glucose was introduced. The cell suspension was then incubated for 15 min with continuous gassing with oxygen or argon and while shaking slowly. When sucrose phosphate was used as the suspending medium, no glucose was added. After incubation, the suspension was transferred to a McNaught tube (A. S. Aloe Co., St. Louis, Missouri), dispersed by forcing through a 14 gauge needle, centrifuged at 270*g* for 20 min, re-dispersed and centrifuged at 1,100*g* for 15 min. The supernatant was removed and the volume of the cell pellet read with an accuracy

* U S Public Health Postdoctoral Fellow.

of ± 5 μl. The inside of the tube above the pellet was wiped many times alternately with damp and dry swabs. The supernatant and cell pellet were diluted with water and the glucose and mannitol extracted by heating in a boiling-water bath for 5 min and the solids removed by centrifugation.

Glucose was determined by the glucose oxidase method ('Glucostat Reagent' from Worthington Biochemicals). When 4,6-dinitro-*o*-cresol was present, appropriate corrections were made for the absorbancy produced by this compound at 420 mμ, the wave-length at which the colour produced in the glucose oxidase reaction is read. The extracellular volume of the packed cell pellet was determined by counting aliquots of the supernatant and cell pellet dissolved in a liquid scintillation mixture in a Nuclear Chicago liquid scintillation counter. The extracellular volume ranged from 83 per cent to 95 per cent. Crane and Mandelstam[2] have reported the extracellular volume of packed villi from hamster intestine to be about 80 per cent.

The millimolar concentration of glucose in the cells was calculated on the basis of the following equation as used by Crane[2]:

$$\text{mM glucose cells} = \frac{\text{Total glucose content of pellet } (\mu\text{moles}) - \left(\text{extracellular space} \times \text{pellet volume} \times \text{mM medium glucose}\right)}{(1 - \text{extracellular space})\,(\text{pellet volume})}$$

The data in Table 1 show that the cells accumulate glucose against a concentration gradient by a process which is energy dependent. The accumulation of glucose varied with different cell preparations which is as expected, and the rate of glucose transport varies along the length of the intestine. Cells were removed from the entire small intestine and in separate experiments various proportions of cells from different regions of the intestine were obtained. Glucose utilization by the cells is much slower than glucose transport. 4,6-Dinitro-*o*-cresol is known to inhibit aerobic phosphorylation[7]. When available cell energy supplies were reduced by anaerobiosis and the presence of 4,6-dinitro-*o*-cresol, transport was inhibited.

We have previously reported on some characteristics of the respiratory metabolism of intestinal epithelial cells suspended in a sucrose–phosphate medium[5]. The sucrose

Table 1. ACTIVE TRANSPORT OF GLUCOSE BY INTESTINAL EPITHELIAL CELLS

Exp. No.	Experimental conditions	Glucose concentration medium (mM)	Glucose concentration cells (mM)	Glucose concentration cells / Glucose concentration medium
(1)	Oxygen	0·8	2 0	2·5
(2)	Oxygen	0·7	5 4	7·7
(3)	Oxygen	0·8	5·0	7·4
(4)	Oxygen	0·8	20 2	25·4
(5)	Argon + 10^{-3} M dinitro-*o*-cresol	0·8	0·5	0·6
(6)	Argon + 10^{-3} M dinitro-*o*-cresol	0·9	1 0	1·1
(7)	Argon + 10^{-3} M dinitro-*o*-cresol	0·9	0 9	1·0

Experiment details are given in the text. The initial glucose concentration of the medium was 1 mM. The cell suspension was incubated at 36° C.

Table 2 GLUCOSE UPTAKE BY INTESTINAL EPITHELIAL CELLS SUSPENDED IN SUCROSE-PHOSPHATE MEDIUM

Exp No.	Cell glucose (mM)	Medium glucose (mM)	Cell glucose / Medium glucose
(1)	79·8	11·5	6 9
(2)	73·0	11·3	6·5
(3)	217·0	4·4	49·3
(4)	42·0	0·7	60·0

Experiments (1) and (2) were carried out at 30° C. Experiment (3) was carried out at 36°. In experiment (4), 0 0058 M sucrose was added to the medium used for cell dissociation and the incubation period in the Warburg was omitted. Other experimental details are given in the text.

was rapidly hydrolysed by invertase present in the brush borders of the cells. It was of interest to see whether the cells would accumulate the glucose formed against a concentration gradient. The results given in Table 2 show that this is indeed the case, though some of the glucose leaked out of the cells or was released from cells that lysed.

Experiments (1) and (2) were carried out at 30° C, while experiment (3) was carried out at 36°. There was a much greater accumulation of glucose at 36° than 30°. In experiment (4) the accumulation of glucose by the cells during cell dissociation was measured. The sodium citrate salt solution contained sucrose. For experiment (4) the cell suspension was centrifuged without any incubation period. The results show that the cells do accumulate glucose against a concentration gradient during cell dissociation and they retain this glucose during centrifugation.

In other experiments not shown, sodium was omitted from the sucrose phosphate medium and glucose uptake measured after 15 min incubation. The cells still accumulated glucose against a concentration gradient. It is not known whether all the sodium ions were washed out as the cells were removed in a sodium-containing medium. Further experiments will be carried out to determine whether the uptake of glucose in the sucrose–phosphate medium is an energy-requiring process.

The results presented in this article indicate that the intact, isolated, intestinal epithelial cells can accumulate glucose by a process that depends on a normally functioning aerobic metabolism. The information obtained here and that which will result from further experimentation will shed much light on the mechanism of cellular transport.

BIOPHYSICAL STUDIES OF A RHINOVIRUS

Ultracentrifugation and Electron Microscopy

THE picornavirus group includes viruses which are very small, ether resistant and contain ribonucleic acid[1]. The rhinoviruses form a sub-group of the picornaviruses[1]. The properties that characterize rhinoviruses are acid lability and optimal growth at 33° C in rolled cultures containing medium with almost neutral *p*H rather than stationary cultures with medium of slightly alkaline *p*H. Some physical properties of rhinoviruses were described by Dimmock and Tyrrell[2,3] and Ketler *et al.*[4]. Using indirect methods, they showed that the size, density and type of nucleic acid were the same as the other picornaviruses. In this and the following article we report further investigations of these biophysical properties by more direct methods. In addition, methods are described for the production of high titre rhinovirus and its partial purification.

The strain of rhinovirus *HGP*[5] used was grown from a terminally diluted preparation. Diploid human embryo lung fibroblast cell strains were used for production of some virus pools and for all assays of infectivity. The cell

strains used were established in this laboratory by Mrs. P. K. Brown. In addition, a line of *KB* cells was obtained from Dr. M. A. Mufson (National Institutes of Health, Bethesda, Maryland) and used for the production of high-titre virus.

Both types of cell were grown in 90 per cent Eagle's minimal essential medium containing 1·1 g/l. of sodium bicarbonate, 100 U./ml. of penicillin *G*, 100 μg/ml. of streptomycin and 100 U./ml. of neomycin and 10 per cent inactivated calf serum. The maintenance medium was identical to the growth medium except that 0·5–2 per cent inactivated calf serum was used.

Production of High Titre Virus

For the success of this work it was necessary to increase the yield of virus per culture. In the first experiment the material collected from one set of cultures was passed serially, without dilution, into further cultures. In addition, we reduced the volumes of medium in the culture vessels (namely, 6 oz. medical flat or 8-oz. baby's feeding bottles, the latter with cells on all sides). Culture fluids and cells were gathered at the time of maximum cytopathic effect, namely 2–3 days after inoculation. The material collected was subjected to cycles of freezing and thawing and sonication to release virus from the cells. Freezing and thawing and sonication resulted in an increase in titre of about $10^{0.5}$ TCD_{50}/ml. only when the cells had not been completely disrupted by the virus. Virus titred to about 10^7 TCD_{50}/ml. in contrast to the titres of about 10^5 TCD_{50}/ml. obtained previously. About this time the virus was adapted to grow in *KB* cells. With a multiplicity of infection of about two infectious units per cell stationary *KB* bottle cultures consistently produced pools with titres of 10^6–10^7 TCD_{50}/ml. Titres were increased by inoculating virus at a multiplicity of about five. By collecting after 1–2 days' incubation and with repeated passages at a high multiplicity, titres of 10^9 TCD_{50}/ml. were achieved. Neutralization tests showed that the virus propagated was in fact *HGP*.

Use of Aluminium Phosphate for Concentration and Purification

Aluminium phosphate was prepared and supplied by Dr. Karl Fantes (Glaxo Laboratories, Ltd.). Fantes[6] has described the use of aluminium phosphate for the concentration and purification of poliovirus. Fantes and Tyrrell (unpublished) found that it was possible to adsorb rhinoviruses to aluminium phosphate. The conditions for the absorption to and elution from aluminium phosphate of *HGP* have now been investigated. The following have been found to give the best results:

(*a*) A final concentration of 0·9–1·0 mg/ml. of aluminium phosphate adsorbs about 95 per cent of the virus from tissue-culture fluids pretreated with fluorocarbon or grown with low concentrations (0·5 per cent) of serum. In the presence of greater amounts of cellular protein or serum more aluminium phosphate is required. Adsorption is performed at a *p*H of 6·8–7·0 at the temperature of melting ice for about 2 h; the mixture is stirred magnetically. The *p*H is adjusted with either 0·1 M sodium phosphate buffer or N/10 hydrochloric acid. In the case of the latter, care must be exercised to add the acid slowly in order to avoid producing a local high concentration of acid which would inactivate the virus.

(*b*) After adsorption the complex of virus and aluminium phosphate is pelleted by centrifugation at 600*g* for 15 min and resuspended in not less than 1/20th of the original volume of 0·5 M sodium phosphate buffer of *p*H 7·9–8·0. Under these conditions and with intermittent shaking, almost all the adsorbed virus elutes at 4° C in 15–30 min. Aluminium phosphate is removed by centrifugation.

Purification and Concentration of a Rhinovirus

About 300 ml. of virus suspension derived from human embryo lung diploid fibroblast cell cultures was filtered through a sintered glass filter to remove cellular debris and ensure sterility. The filtrate was adsorbed with 30 ml. of a suspension of aluminium phosphate gel (containing 9·0 mg/ml. aluminium phosphate) as already described and eluted into 150 ml. of sodium phosphate buffer. The eluted virus was deposited by centrifugation at about 78,000*g* for 3 h at 4° C. The deposit was resuspended by rubbing with the tip of a sterile glass rod and sonication. The virus was finally resuspended in Hanks's saline containing 1 mg/ml. gelatine as a stabilizing agent. The virus suspension was blended with an equal volume of fluorocarbon ('Arcton 113'—Imperial Chemical Industries, Ltd.) for 2–4 min at ambient temperature and the aqueous and fluorocarbon layers were separated by centrifugation at 600*g* for 15 min. Caesium chloride was added to the aqueous layer. The solution was then centrifuged in an M.S.E. 'Superspeed 40' preparative ultracentrifuge in the 3 × 5 ml. swing-out rotor for 38 h at 4° C at about 111,000*g*. No brake was used. By this means an equilibrium density gradient was established. Fractions of 0·2 ml. were removed from the meniscus, from each centrifuge tube. One tube was used for infectivity measurements, one for density measurements and the third for electron microscopy. All these manipulations were performed without delay.

Densities of the caesium chloride gradient fractions were calculated from their refractive indices measured in an Abbé refractometer at room temperature, using the formula: $\rho 25 = 10{\cdot}8601.\ \eta_D^{25} - 13{\cdot}4974$ where $\rho 25$ = density at 25° C, η_D^{25} = refractive index of the *D* line of sodium at 25° C. The reading of refractive index was corrected to 25° C from room temperature using the correction of 0·0001 refractive index units for every degree centigrade difference in temperature.

Titrations of infectivity at the various stages of purification and of all the fractions from the density gradient were carried out by the microplaque technique[7].

Fractions from the gradient were examined in a Siemens 'Elmiskop I' electron microscope at an accelerating voltage of 80 kV with 200μ condenser and 50μ objective apertures. Fractions for electron microscopy were prepared using Harris's vibrating reed technique[8]. After the samples had dried on the carbon-coated 'Formvar' grids they were washed in distilled water to remove caesium chloride and then stained with 0·5 per cent phosphotungstic acid at *p*H 6·8 (ref. 9). Survey examinations were carried out at magnifications of 20,000 and micrographs taken at 80,000. The results obtained are shown in Figs. 1 and 2.

A gradient was produced which had a range of density of 1·264–1·459. Virus-like particles were seen in fractions with a density of 1·307. They were associated with no infectivity. A large number of virus-like particles were seen in the fraction with a density of 1·404. Most of the infectivity was detected at this point.

Similar results were obtained in a second experiment which differed from the first experiment in the following particulars. The virus suspension was grown in *KB* cells and cellular debris was removed by centrifugation at 600*g* for 15 min. Before adsorption to aluminium phosphate the tissue-culture fluid was blended with an equal volume of fluorocarbon. Aluminium phosphate was added to the aqueous layer to a final concentration of 2·0 mg/ml. and the mixture stirred for 2 h. The aluminium phosphate and adsorbed virus were deposited by centrifugation and eluted for 2 h at 4° C. An equal volume of Hanks's saline containing gelatine was added to the eluate, which was clarified by centrifugation at 7,000*g* for 15 min. After deposition and resuspension of the virus, and treating it with fluorocarbon, 6·3 g caesium chloride was added to 15 ml. of virus suspension. The mixture was centrifuged to equilibrium at 111,000*g* for 24 h. Fractions were removed as before, but instead of keeping three sets of fractions (one from each centrifugation tube), equivalent fractions were pooled and 0·2 ml. of each pool was put into 1·8 ml. of Eagle's minimal essential medium con-

taining 2 per cent heat-inactivated calf serum and kept for infectivity measurements. A gradient of 1·314–1·490 was achieved. Once again two groups of particles were seen in the electron microscope and these occurred at about the same densities as in the previous experiment. A single peak of infectivity was found in the fraction with a density of 1·401.

In both experiments infectivity was lost during the density gradient run. It has been found in other experiments that *HGP* is unstable in caesium chloride solutions. Measurements of the diameter of virus particles (Table 1) confirm the value previously found by ultrafiltration[3].

Poliovirus has a buoyant density of 1·32 (ref. 10). Because of the similarity in size and the fact that the sedimentation rates are identical[3], it has been assumed that *HGP* must have a density of the same order as poliovirus. However, direct measurement of the buoyant density in the present work seems to indicate that *HGP* is more dense than poliovirus. Indirect evidence indicates that capsomeres of *HGP* are not held together so tightly as those of poliovirus. For example, the acid lability[3] and the sensitivity of *HGP* to urea[11] contrast with the relative stability of poliovirus under these conditions[3,12]. Thus it is possible that caesium chloride can penetrate *HGP* more readily than poliovirus and by this means increase its buoyant density. The density of the non-infectious *HGP* was much nearer that observed for poliovirus[10]. The differences in density observed between infectious and non-infectious *HGP* are much greater than observed for other picornaviruses, for example, echovirus 11 (ref. 11) and echovirus 12 (ref. 13). It is interesting to note that

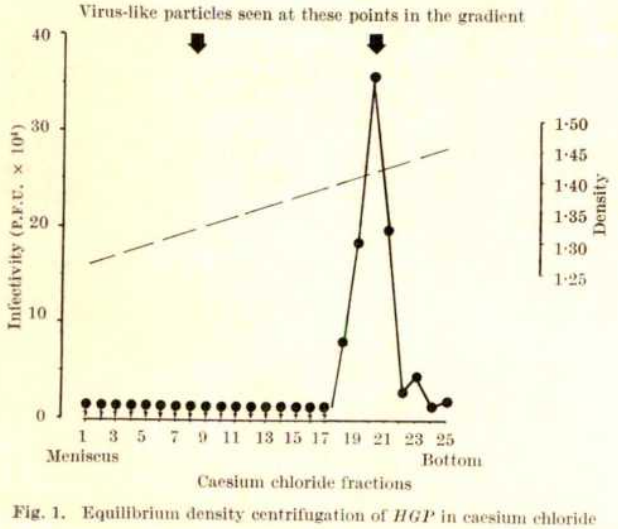

Fig. 1. Equilibrium density centrifugation of *HGP* in caesium chloride

Experiment	'Full' No. counted	'Full' Mean ± 3 *S.D.*	'Empty' No. counted	'Empty' Mean ± 3 *S.D.*
1	9	315 ± 16 Å	6	302 ± 27 Å
2	40	295 ± 10 Å	35	304 ± 14 Å

S.D. = standard deviation of the distribution of particle diameters.

after staining with phosphotungstate, samples of the high- and low-density fractions both contained approximately equal numbers of apparently 'full' and 'empty' particles. This would suggest that some particles appear 'empty' because they are permeable to phosphotungstic acid and not because they lack ribonucleic acid.

The micrographs obtained so far reveal little of the substructure of the virus, although it has been reported that another rhinovirus probably has icosahedral symmetry[14].

Extraction and Assay of Infectious Ribonucleic Acid

It is believed that all picornaviruses contain infectious ribonucleic acid (RNA), which has indeed been extracted from many enteroviruses. Rhinoviruses are also classified within the picornavirus group and it has been shown that halogen-substituted pyrimidine analogues failed to inhibit their replication. It is therefore assumed that they also contain RNA. Detailed accounts of the extraction and assay of infectious RNA from representatives of the polioviruses, coxsackieviruses and echoviruses have been given[1,2], but there is only a brief report[3] on the recovery of infectious RNA from one of the rhinoviruses (*C.V.*11), which grows only in human cells (an *H* strain). This article presents direct evidence that the rhinovirus *HGP*,

a *b* *c*

Fig. 2. Phosphotungstate preparation of rhinovirus particles. (*a*) Typical 'full' particles (× 200,000); (*b*) typical 'empty' particles, one of which is apparently unfolded (× 200,000); (*c*) a higher magnification of an 'empty' particle showing a hexagonal outline and a roughly circular inner cavity

which grows in both human and monkey cells and is therefore an *M* strain, possesses infectious RNA. Its extraction from infectious tissue-culture fluid and its assay are described and it is demonstrated that its infectivity has properties that are quite different from those of the original virus.

HGP was grown in monolayers of *KB* cells held stationary at 33° C (ref. 4). The majority of cells showed cytopathic effect within 48 h. Culture fluids were collected, subjected to ultrasonics and clarified by centrifugation at 500*g*. The virus titred about $10^{6.7}$ $T.C.D._{50}$/ml. in a sensitive human embryo lung (*HEL*) cell strain.

Before extraction the virus was mixed with washed bentonite (Hopkin and Williams, Ltd., Chadwell Heath), which has been shown to inhibit the action of contaminating ribonuclease[5]. The quantity of bentonite used (about 8 mg/ml.) was sufficient to preserve poliovirus RNA infectivity in the presence of non-infectious culture fluid prepared in parallel with virus. The extraction process was a modification of the cold phenol method of Gierer and Schramm[6] and was carried out so far as possible at 4° C.

Ethylenediamine tetraacetic acid ('AnalaR', B.D.H., Ltd., Poole) was added to the virus to a final concentration of 0·001 M before extracting with phenol. Bentonite was present at all times. Dissolved phenol ('AnalaR') was removed with freshly distilled ether ('AnalaR') and the ether blown off with nitrogen. The extract was stored with bentonite at −70° C.

The choice of cells for an infectivity assay was governed by their availability. The 'Bristol' HeLa line (obtained from Dr. S. K. R. Clarke), in which the assay of the infectious RNA of poliovirus had been studied in some detail, was chosen. The cells were grown in Hanks's balanced salt solution containing 10 per cent heat-inactivated rabbit serum, 0·1 per cent lactalbumin hydrolysate, 0·1 per cent sodium bicarbonate and antibiotics. As an assay for infectious RNA is highly specific for a particular cell system[2], the poliovirus RNA-'Bristol' HeLa system was used without alteration for the assay of *HGP* phenol extract. However, *HGP* virus grew poorly in monolayers of these cells held stationary at 33° C and did not produce a visible cytopathic effect. The presence of virus was detected by inoculating HeLa culture fluid into *HEL* monolayers which were rolled at 33° C.

The infection of cells was based on the method evolved by Alexander[1] where the phenol extract was suspended in hypertonic saline. HeLa monolayers in 50-mm plastic Petri dishes (Grade *A*, Esco (Rubber), Ltd., London) were washed twice in Hanks's balanced salt solution containing 0·06 per cent sodium bicarbonate and no calcium and magnesium ions, and a third time in the same medium containing 0·5 M sodium chloride. Bentonite was removed from the *HGP* phenol extract by centrifuging at about 500*g* and the extract was suspended in M sodium chloride in 0·01 M *tris* (hydroxy-methyl) amino methane (*p*H 7·1). Volumes of 0·2 ml. of serial two-fold dilutions were inoculated on to the monolayers for 10 min at room temperature. 5 ml. of 2 per cent heat-inactivated calf serum in Eagle's minimum essential medium with antibiotics was added at the end of this time and the dishes were incubated at 33° C for 4 days in a humidified atmosphere of 5 per cent carbon dioxide in air. The fluids of each pair of monolayers were then pooled and 0·5 ml. was inoculated into each of three *HEL* monolayer tubes. A cytopathic effect in one or more monolayers was taken to indicate that the original extract was infectious. The cytopathic effect resembled that of *HGP*. Infectivity of the phenol extract was abolished by incubation for 15 min at room temperature with 10 μg/ml. ribonuclease (L. Light and Co., Ltd., Colnbrooke). The virus which grew up in *HEL* monolayers was neutralized by antiserum to *HGP*.

The titre of the extract was usually about 4 $\log_{10}$ less than that of the original virus. Other phenol extracts of picornaviruses which have been titrated in a similar manner by other workers showed a comparable loss of infectivity[1,2]. The infectivity of *HGP* phenol extracts persisted without loss for more than 2 months at −70° C.

An attempt was made to neutralize infectivity of the phenol extract to determine whether or not it was associated with active virus antigen. Phenol extract or virus of the same titre was mixed with *HGP* monkey antiserum (*B.W.*195) or phosphate-buffered saline and was incubated at room temperature for 30 min. An equal volume of phosphate-buffered saline or 2 M sodium chloride in 0·01 M *tris* was added to the virus mixtures which were assayed respectively in *HEL* monolayer tubes or exactly as phenol extract. Virus infectivity, assayed by either technique, was completely neutralized and the infectivity of the extract was not affected (Table 1).

The failure to neutralize the infectivity of the extract could have been caused either by damaged antigen, possibly denatured by phenol, or by absence of the antigen. If the latter were correct the infectivity of the extract would sediment at a slower rate than *HGP*. The rate of sedimentation of the extract suspended in phosphate-buffered saline was determined by centrifuging at 75,000*g* for 30 min in the swing-out head of the M.S.E. 'Superspeed 40' preparative ultracentrifuge. (The suspension contained bentonite which would be pelleted within the first minute of centrifugation.) At the end of the experiment, consecutive 0·5 ml. fractions were taken from the top of the tube and immediately placed in bentonite. Table 2 shows that the titre of all fractions was 0·3 $\log_{10}$ less than that of the uncentrifuged control. This may have been caused by aggregations, which would sediment more rapidly, or by infectivity being carried down with the bentonite. Otherwise, the infectivity of the extract was not sedimented appreciably. In comparison, after centrifugation by the same method in a concentration gradient of 0–9 per cent sucrose, all virus infectivity was found in the lower half of the tube. It is concluded that the infectivity of the phenol extract is associated with little virus antigen.

In summary, the infectivity remaining after extraction of *HGP* with cold phenol was about 4 $\log_{10}$ less than the original virus. It was inactivated by ribonuclease, was unaffected by antiserum which neutralized the virus and was not sedimented under conditions which sedimented the virus. Culture fluids from HeLa cells inoculated with the extract produced a cytopathic effect in *HEL* cells resembling that of *HGP*. The resulting infectivity was neutralized by antiserum to *HGP*. It is concluded that the infectious agent was *HGP* ribonucleic acid.

Table 1. Effect of *HGP* Antiserum on the Infectivity of an RNase-sensitive Phenol Extract of *HGP*

EXPERIMENTAL TRANSMISSION OF A KURU-LIKE SYNDROME TO CHIMPANZEES

By Dr. D. C. GAJDUSEK, Dr. C. J. GIBBS, jun., and Dr. M. ALPERS
National Institute of Neurological Diseases and Blindness, National Institutes of Health, Bethesda, Maryland

A CLINICAL syndrome astonishingly akin to kuru in man has developed in three chimpanzees from 18 to 21 months after intracerebral inoculation with brain suspension from different kuru patients. This fatal syndrome with progressive cerebellar ataxia and incoordination has not been seen as a spontaneous disease of apes, and is the first convincing indication of the transmissibility of one of the sub-acute or chronic human central nervous system diseases under investigation in our programme.

In an earlier communication[1] we described our programme of work on the possible infectious aetiology of sub-acute and chronic human central nervous system diseases and presented negative results on isolation and experimental transmission following 19 months of observation. The purpose of this article is: (*a*) to present details of the apparent transmission of kuru to chimpanzees and of our present efforts at virus isolation from tissues from these animals and from kuru patients (Table 1); (*b*) to provide further information and generally negative results on our expanded experimental studies after an additional 17 months of observation, that is, at 3 years after initiation of primate inoculations (Table 2). Because of continuing reports from other laboratories[2] of transmission of chronic progressive nervous system disease to animals from certain of the neurological diseases under investigation, this second progress report of our negative results, with the notable exception of kuru, is in order.

A year ago at a 'workshop-symposium' on "Slow, Latent and Temperate Virus Infections", held at this laboratory[3], details of the inoculation of laboratory animals, particularly primates, and tissue cultures with tissue from patients suffering from a number of chronic neurological diseases were presented. The diseases under study included kuru, amyotrophic lateral sclerosis, parkinsonism, parkinsonism-dementia, sub-acute inclusion encephalitis (Dawson's), myasthenia gravis, multiple sclerosis, Schilder's disease, progressive multifocal leucoencephalopathy, and necrotizing encephalitis. However, at that time there was still no evidence of a progressive degenerative nervous system syndrome developing in any of the primates under observation[4,5].

Our techniques have emphasized the collection and optimal preservation of blood, brain and other tissues at early autopsy or by surgical biopsy procedures for animal and tissue culture inoculation, for cultivation of live cells from explants, or for use as sources of antigens. Suspensions of these tissues are then inoculated into a variety of primates and other experimental animals, as well as an extensive array of tissue and cell cultures. Animals are held in isolation and observed for periods of more than 5 years. Additional virological techniques, for example, blind passages, the search for sero-conversions by estimation of antibodies to known viruses, and the search for viral antigens or reagents in tissues and tissue cultures by a variety of immunological methods, including fluorescent antibody, are being used in an effort to detect the presence of infectious entities.

The intracerebral inocula used in and the date of inoculation of the three chimpanzees which have developed kuru-like clinical syndromes, and the data on the remaining five animals still under observation without illness are summarized in Table 1. It is noteworthy that the incubation period in the three affected animals has ranged only between 18 and 21 months and that the course to killing in the terminal stages has been 5 and 9 months in the first two animals. Most remarkable, however, is the close similarity in the clinical appearance of the syndrome in the chimpanzee to kuru in human patients. To document and preserve this clinical record extensive use has been made of the 'research cinema film' technique[6], and several research films are in preparation documenting the progress of the disease in chimpanzees[7].

First chimpanzee (Georgette, tattoo No. 4). Female, about 2 years old. Inoculated with Eiro 10 per cent brain suspension, 0·2 ml. intracerebrally, in September 1963. Eiro (Eiru) (male, aged 13) died in September 1962; brain material was taken and frozen within 4·5 h of death, kept in a refrigerator (−10° C) or dry ice until placed at constant −70° C 60 h after death; the pathology of this patient has been reported[8]. In May 1965 the chimpanzee first showed signs of apathy and lassitude, which progressed and within a month was accompanied by a pendulous lower lip, increased sensitivity to cold, and pilo-

* In addition to the primary isolation inoculation a further three chimpanzees were inoculated in October 1965 in an attempt at re-isolation and three other chimpanzees were inoculated with brain from the first killed animal

† In addition all primates inoculated with suspension of human brain tissue as summarized in Table 2 serve as controls. All chimpanzees and more than 100 monkeys are housed in the same building. The facilities provide the animals with adequate space for daily exercise outside of their individual cages.

erection. Within two months she demonstrated titubation and trunkal unsteadiness, a wide-based, lurching gait and, later, marked dysmetria of hand movements. Her ataxia became more severe and she suffered many stumbles and falls. Eventually she was unable to sit up without external support and spent her time huddled at the bottom of her cage. She required encouragement to eat and drink, but only terminally was there any difficulty with swallowing. Visual fixation became impaired terminally. Hearing appeared normal. There was no spontaneous nystagmus but it could be elicited by vestibular stimulation. At no time was there any motor paresis, though power was poorly sustained; passive limb tone was normal or decreased. There was no loss of pain sensation; hyperaesthesia to touch occurred over the last 6 weeks of her illness. Detectable reflex changes, changes in the fundi, convulsions, impairment of consciousness or obvious disorientation did not occur. Haematological, biochemical and trace metal determinations on the blood were considered normal. Cerebrospinal fluid collected just before death was clear with a protein level of 237 mg/100 ml. Progressive ataxia involving the trunk and all limbs and leading to increased disability remained the chief feature of the syndrome. She was killed in October 1965, when her terminal debility, dysphagia and respiratory distress caused our concern lest sudden death from secondary infection should intervene.

Second chimpanzee (Daisey, tattoo No. 1). Female, about 2 years old. Inoculated with Kigea 10 per cent brain suspension, 0·2 ml. intracerebrally, in August 1963. Kigea (female, aged 11) died in March 1963; brain material was taken 1 h after death, frozen within 6 h, and kept frozen in a refrigerator (− 10° C) or dry ice until placed at constant −70° C 80 h after death; the pathology of this patient will be reported[9]. In May 1965 the chimpanzee first showed definite signs of withdrawal and apathy having previously been a very friendly, open and affectionate animal. This stage lasted for 3 months without significant change. Then titubation, trunkal instability, ataxia of gait and dysmetria of hand movements began and slowly increased in severity. Lethargy, apathy and poverty of movement persisted; at times, huddled on the shelf of her cage, she maintained slowly evolving postures in an almost catatonic state. Small stimuli, however, would lead to an exaggerated startle reaction. Tendon reflexes were diminished but not absent; passive limb tone was increased. There were no detectable sensory deficits, nor motor pareses. Terminally, an inconstant strabismus appeared; there was no nystagmus. Vestibular function and hearing appeared normal. There were no changes in the fundi, and no convulsions occurred. By late December 1965 she reached the same terminal state as the first chimpanzee, huddled in the bottom of the cage with her arms around her trunk, grossly ataxic on any attempted movement, and showing impairment of visual fixation and increased dysphagia.

Third chimpanzee (Joanne, tattoo No. 9). Female, about 2 years old. Inoculated with Kabuinampa 10 per cent brain suspension, 0·2 ml. intracerebrally, in February 1964. Kabuinampa (female, aged 23) died in December 1963; brain material was taken within 1 h of death and placed in liquid nitrogen; the pathology of this patient will be reported[9]. In August 1965 the chimpanzee first appeared lethargic and apathetic, had a pendulous lower lip, sustained pilo-erection, and frequent shivering which never became paroxysmal. Within a few weeks signs of motor inco-ordination, titubation, trunkal instability, dysmetria and an unusual wide-based stamping gait, in which she never rose much above her haunches, developed. Muscles undergoing sustained contraction showed a marked clonic tremor. Occasional shivering-like tremors were seen. There have been no motor pareses or reflex changes. Hearing, vision and extraocular movements have appeared normal. She has had no convulsions. She has remained lethargic and shows little spontaneous voluntary movement; but she greatly resents handling and examination, to which she responds with wide facial grimacing and a monotonous shrill cry. Her ataxia has progressed steadily and she has followed a course strikingly similar to that of the first chimpanzee.

On the 160th day after the recognized onset of disease in the first chimpanzee (in October 1965) the original 10 per cent brain suspension (stored at −70° C) which had been inoculated into this animal was re-inoculated into three new young chimpanzees (two male, one female). When this first affected chimpanzee was killed on the 163rd day of illness, generous portions of blood, brain and visceral tissue were taken and stored in liquid nitrogen, using separate sterile instruments for each tissue. A freshly prepared 10 per cent suspension of unfrozen brain material, pooled from three brain areas, was inoculated intracerebrally into three young male chimpanzees and a number of individual monkeys of several species. Further chimpanzees will be inoculated with blood and with suspensions of visceral tissue and these tissues and brain will be titrated as the supply of animals permits. Filtrates of brain suspension through filters of various pore size will be inoculated into chimpanzees in an attempt to establish whether the agent involved is a filterable virus, for to date only centrifugally clarified tissue suspensions (2,000 r.p.m./20 min) have been used and thus non-viral micro-organisms remain an aetiological possibility, although conventional bacterial and fungal cultures as well as tissue culture passage of the inocula have proved sterile. A few chimpanzees will be inoculated only subcutaneously, not intracerebrally, with brain suspension.

When the first chimpanzee was killed no gross neuropathological lesion other than a fine needle scar at the site of the inoculation in the frontal lobe was observed. Preliminary histological study by Mrs. Elisabeth Beck (Department of Neuropathology, The Maudsley Hospital,

† CNS, Central nervous system.

‡ Date given is that of the initiation of the inoculation programme with each disease; the number is the total number of animals inoculated up to February 1966.

§ A strain of herpes simplex virus was isolated in tissue culture from the specimen, the single rhesus monkey inoculated intracerebrally has not developed illness.

London) has revealed the diffuse non-specific changes seen in the brains of kuru victims together with the cerebellar system degeneration characteristic of the disease. Detailed neuropathological studies are in progress[10].

We continue to observe the remaining five kuru-inoculated chimpanzees, inoculated 30, 29, 27, 27 and 24 months ago, respectively, and the many smaller monkeys of other species which have been inoculated with kuru material intending to hold these animals for at least 5 years of observation. The three animals which have developed kuru-like syndromes have all been females, as are three of the five kuru-inoculated chimpanzees still well. (*Addendum.* Since this article was written, one male chimpanzee of the two inoculated in November 1963 with brain material from patient Kariwani has developed, in mid-January 1966, the same kind of progressive ataxia described in the three earlier chimpanzees.) Efforts are being concentrated on cultivating an agent in a wide variety of tissue cultures, in chick embryos and many different young laboratory animals, and on identifying a viral antigen in tissues from the affected chimpanzees and from human patients, and in passage animals and cultures by immunological methods.

In view of the close similarity in the clinical picture and the neuropathological findings of kuru in man with those of scrapie in sheep and mice[11,12], the remote possibility of scrapie infection in the affected chimpanzees must be considered, although so far there is no evidence of the scrapie virus producing disease in primates. All primates inoculated with human material are housed in a remote, separate building from that in which scrapie investigations are being carried out. Of nineteen chimpanzees and more than 200 smaller monkeys in these transmission experiments from human tissue no animals have developed a chronic progressive neurological disorder, other than the three kuru-inoculated chimpanzees described here. *Macaca rhesus* monkeys inoculated 18 months ago with scrapie mouse brain suspension have not yet shown disease. Chimpanzees are only now being inoculated with scrapie material.

To anyone who has had the opportunity of observing the unique syndrome of kuru developing and progressing steadily to fatal termination in patients in New Guinea, the similarity of its clinical picture and course to the experimentally induced syndrome in the chimpanzee is dramatically evident. This remarkable clinical correspondence of a disease developing successively in three chimpanzees each inoculated with brain material from a different kuru patient, the onset in each after a very similar long incubation period, the fact that there is no such syndrome of chimpanzees known to occur spontaneously or seen at present in our many control animals, and the remarkable similarity of the neuropathological findings, in the one case examined, to those observed in kuru victims lead us to believe that kuru has been transmitted experimentally to these chimpanzees.

KINETICS OF TWO-BREAK CHROMOSOME EXCHANGES AND THE SPATIAL ARRANGEMENT OF CHROMOSOME STRANDS IN INTERPHASE NUCLEUS

By Dr. SUSHIL KUMAR and Dr. A. T. NATARAJAN

Division of Botany, Indian Agricultural Research Institute, New Delhi-12

ONE of the consistent observations in radiation cytology has been that the yield of two-hit chromosome exchanges, whether detected genetically as translocations or cytologically as dicentrics and rings, increases not as the square of the dose but by about the 1·5th power of the dose[1-3]. It has been known that for aberration production the breaks in two chromosome strands should occur sufficiently close together in space for rejoining, other than restitution, to occur[4]. Wolff[3,5] has recently developed an equation, to formulate the spatial restriction in terms of a limited number of sites in which the chromosomes come within the rejoining distance, to describe the theoretically expected kinetics for the two-hit chromosome exchanges. Earlier explanations for anomalous kinetics of two-break aberrations considered the occurrence of a large amount of inviability appearing at high doses or a large linear component[6] to be the reasons for falling off of the dose response curves from the dose square approximation at high doses. In the experiments reported here, the dose-response has been examined separately for dicentrics and centric rings. The results have suggested an interpretation of over-all response and permitted us to put forth a model concerning the spatial organization of chromosomal strands in the interphase nucleus.

Dry barley seeds (*Hordeum vulgare cv CN* 292, $2n = 14$; hull-less; moisture content, 10–12 per cent) were used in this investigation. With dry seeds, the post-irradiation environment during germination can be effectively controlled. The seeds were given doses of γ-rays at 5·1 kr./min in cobalt-60 'Gamma Cell 200' (Atomic Energy of Canada, Ltd.) at our laboratory and of fast neutrons (mean energy ≃ 1 MeV, γ contamination negligible) at reactor R_1 of the Swedish Department of Atomic Energy, Stockholm. The irradiated seeds were hydrated in the presence or absence of oxygen at 0°, 20° and 30° C for 24 h and then germinated on moist filter paper at 25° ± 2° C. The yield of dicentrics and rings was evaluated at colchicine-blocked first mitosis, from Feulgen-stained squash preparations. The data from five replications from each post-irradiation treatment were pooled together. For the doses investigated, the distributions of two-break aberrations have been observed to be Poisson at low doses and non-Poisson—with tendency towards normality—at high doses, and this indicates the absence of limitation

Table 1. Effect of Doses of γ-Rays and Fast Neutrons on Yields of Dicentrics/Cell, Rings/Cell and Dicentrics+Rings/Cell

Radiation/dose	Dicentrics/cell	Rings/cell	Dicentrics+rings/cell	Dicentrics/Rings
Fast neutrons				
200	0·221	0 023	0 244	9·6
400	0 361	0 044	0 405	8·2
600	0 433	0 069	0·502	6·3
800	0·589	0·092	0·681	6·4
Kinetics	$D^{0\cdot89}$	$D^{0\cdot95}$	$D^{0\cdot83}$	
	$D^{0\cdot82}$	$D^{1\cdot05}$	$D^{0\cdot84}$	
γ-rays/(kr.)				
25	0·229	0·050	0·279	4·6
37·5	0 340	0 106	0·446	3·2

Kinetics	$D^{1\cdot33}$	$D^{2\cdot20}$	$D^{1\cdot49}$	

on the number of sites for aberration formation in interphase meristematic cells of dry barley seed[7].

The effect of dose on yields of dicentrics/cell, rings/cell and dicentrics + rings/cell is given in Table 1. The yield of rings/cell is proportional to the dose with fast neutrons and to the square of the dose with γ-rays. These data show that in a site forming a ring, where two arms of a chromosome come within the rejoining distance, the two strands are broken by the same ionizing particle to give one-hit kinetics with fast neutrons and by two different ionizations to give two-hit kinetics with γ-rays. However, the kinetics for dicentrics/cell are such that the yield increases by less than a factor of 2 with fast neutrons and by less than a factor of 4 with γ-rays. Since kinetics in terms of initial ionization (or hits) by sparsely—or densely—ionizing particles must be the same irrespective of whether the site forms a ring or a dicentric, the reasons for wide differences in kinetics for rings and dicentrics have to be found in the distribution and structure of nuclear sites for rings and dicentrics.

If the arrangement of chromosomes in the interphase nucleus is random and sites for dicentrics and rings are formed randomly, then in barley, which has a symmetrical karyotype containing 28 chromosome arms, the expected ratio of dicentric-forming sites to ring-forming sites will be 26 : 1. The experimentally observed ratio varies between 9·6 : 1 and 2·8 : 1 (Table 1). This indicates that the arrangement of the two arms of a chromosome may be such that they come near each other more frequently than would be expected on the basis of random arrangement.

The examination of the characteristics of the radiation-induced aberrations in barley revealed that (1) most dicentrics carried a small intercalary segment and were accompanied by a big acentric fragment; (2) dicentric rings carried a very small intercalary segment. The aberration configurations with small intercalary segments can arise only if the centromeres of the chromosome strands involved in an aberration are situated close to one another. These results indicate that the centromeres in the interphase nucleus are strongly polarized. A similar conclusion was arrived at by Sax[8], from observations in *Tradescantia* where unequal interchanges induced by radiation were found to be rare, and more than 80 per cent of the interchanges were found to involve exchanges between the chromosomes or chromatids at corresponding loci in respect of the distance from the centromere. Evans's data on interchanges in *Vicia faba* indicate that 80–90 per cent of the interphase chromosomes are polarized[9]. The model of interphase nucleus under consideration, then, has the following features: (1) the chromosome strands are strongly polarized; (2) the chromosome arms radiate from the centromeric pole at a small angle; (3) the chromosome strands are located in definite and recurrent sites.

This model gains support from the observation that relatively little displacement occurs following uncoiling and elongation of chromosomes and during the succeeding interphase so that chromosome strands reappear in the prophase in the same place as they were at the preceding telophase. If the three characteristics listed here apply to telophase chromosomes, then they must also apply to chromosomes in the static interphase as well.

It follows from the properties of the interphase nucleus that the average strand to strand distance would be least at the polar end and maximum at the free end. The chances, therefore, of chromosome strands coming within the rejoining distance and forming a site are higher near the pole than away from it. We would expect this feature to have an effect both on the number of sites and number of strands forming a site. Thus (1) near the pole end, a far greater number of sites is formed than away from it; (2) a large majority of sites formed near the pole involve more than two strands. Since most of the dicentrics carry small intercalary segment and accompany large acentrics and most rings accompany small acentrics, it can be predicted that a greater proportion of the dicentric-forming sites are formed near the pole and a majority of ring-forming sites occur away from the pole towards the free ends of chromosome strands. It would appear from postulate (2) that a site has to be imagined as a spherical volume of diameter of rejoining distance. Within this sphere two or more than two strands can be included.

Only two chromosomes are required to be broken for an exchange to be produced. The chance of getting two independently broken chromosomes with sparsely ionizing radiation in a bi-stranded site will be different from that in a tri- or a multi-stranded site. The chance will be the product of the probabilities of breaking individual chromosomes multiplied by one less than the number of strands included in the site, that is $(s-1)p^2$, where s is the number of strands included in a site and p is the probability of breaking a chromosome in a site. The yield for two-hit exchanges within site will vary with s, it will be proportional to dose if $s = 2$ and to a less power of dose if $s > 2$. The average kinetics will have contribution of each of different kind of dose-response terms. These considerations indicate that the majority of dicentric-forming sites would have to be multi-stranded and all ring-forming sites bi-stranded.

The presence of additional breaks in a site will affect the probability of asymmetrical rejoining with fast-neutron radiation if the probability that a bi-stranded site becomes effective is q; the probability that a tri-stranded site becomes effective is $3q$. The chances of reunion to take place will be still higher if the sites overlap and chromosomes are broken in overlapping sites. Thus, with the increased probability of rejoining at higher doses of fast neutron radiation, the yield for two-hit exchanges within a site will not be proportional to dose, but to less than one power of the dose. This component of dose response evidenced with densely ionizing radiation will also affect the kinetics with sparsely ionizing radiation.

The expressions for yields of aberrations in bi- and tri-stranded sites can be given as:

	Bi-stranded site	Tri-stranded site
Fast neutrons	$Y = k\,(D)\,q + c$	$Y = k\,(D)\,Q + c$
γ-rays	$Y = k\,(D^2)\,q + c$	$Y = k\,(2D^2)\,Q + c$

where k is the mean number of breaks in a chromosome in a site/rad, D is the radiation dose, Q the probability of asymmetrical rejoining at a site as affected by post-irradiation environment (q) and influence of additional breaks, and c number of spontaneous exchanges observed at zero dose.

The foregoing equations have been derived on theoretical as well as experimental grounds and provide an estimate of the expected yields of exchanges within a site as the dose changes. The expressions for yield of aberration in sites with higher number of strands can be similarly obtained. In deriving these equations it has been assumed that sites do not overlap, and that there is no effect of multiple breaks in a strand within a site. In the present investigation the influence of these two factors could not be evaluated. This investigation also suggests that a general formulation on the kinetics of two-break chromosome aberrations should take into consideration the size of chromosome complement, nuclear volume and nature of karyotypic symmetry.

We thank Dr. M. S. Swaminathan for valuable discussions, and the Council of Scientific and Industrial Research, India, for a pre-doctoral fellowship to one of us (S. K.).

LETTERS TO THE EDITOR

ASTROPHYSICS

Lightning, Novae and Quasars

Quasars 'or something' have been a desideratum of the electrical discharge theory of cosmic atmospheric phenomena and universal evolution since its inception in 1941, and the absence of any reference to galaxies which are radiating an inordinate amount of energy was one of the main difficulties facing the theory. As the years went on, I had to conclude that the energy must be largely in the unobservable range, for example, X-rays or γ-rays. However, in the original outline of these ideas published in 1944 (ref. 1*a*), I emphasized that galaxies exist which possess an emission line spectrum, and that in all probability they are those which the theory required. In a recent review article[2] on quasars, this is still their only optical characteristic mentioned.

On the theory, they are analogous to the naked eye phase of novae, that is, they represent the phase around peak current in the discharge[1*b*], during the neutralization of the electric field built up slowly during lifetime of a star or galaxy, probably by asymmetrical impacts between grains[1*c*], though the exact nature of these field-building processes is not yet agreed even in thunderclouds[1*d*].

In a paper presented to the second U.S. Air Force Conference on Atmospheric Electricity in 1958 (ref. 1*e*) I pointed out that this phase of the discharge lasts for about 10 μsec in the lightning discharge, from 1 to 10 min in a solar flare[1*f*], about 10 days in a nova[1*b*], and might be expected to last for 10^6 years in the corresponding galactic discharge. However, if, as seems reasonable in view of the geometrical similarity between the two cases, we assume that this phase will occupy a similar fraction of the total life of the outburst on the stellar and galactic scales, we obtain an estimate of 10^4–10^5 years for the peak current phase of the galactic discharge, which agrees well with Greenstein's range of estimates of 10^3–10^7 years for the duration of quasars[3].

Another characteristic which quasars and novae have in common is the extreme rapidity with which their radiation can vary during the outburst, due very probably to the pinching out of the discharge. In Nova Hercules 1934, for example, the brightness of the star fell abruptly by about nine magnitudes soon after its peak. Thereafter its brightness increased somewhat more slowly until it approached its pre-extinction value.

From the photographs[4] of the well-known 'jet' or discharge channel in the radio source Virgo *A*, *NGC*4486, it would appear that these pinches also occur on the galactic scale, since the jet is divided into three 'sausages' by the pinching of the channel in two places.

A corresponding phenomenon was recently photographed in the lightning flash[5], so these varied observations would appear to afford another interesting link-up between phenomena on these three very different scales[1*g*].

The characteristics of the phenomena will be different from those already considered in relation to the pinching of laboratory discharges, as we have now to consider the breakdown of an electrostatic field[1*h*,*j*]. As indicated in the recent article just referred to[1*g*], huge electrostatic as well as electromagnetic forces are involved.

It may also be noted that the discharge theory of necessity introduced circular magnetic fields in and around the spiral arms of the galaxies from its initiation in 1941. In 1953 magnetic fields along the arms were introduced by Chandrasekhar and Fermi[6], but as Cowling emphasized[7], without a proposed origin of these fields, that did not take us much farther. However, in 1961 it was proposed[8] to transform these last fields into circular fields around the arms in agreement with those originally introduced in 1941 by the electrical discharge theory.

Furthermore, in 1961 (ref. 1*k*) I estimated the total energy liberated by a radio galaxy as 10^{60} ergs when the value available for comparison, derived from Virgo *A*, was 10^{58} ergs (ref. 9). From a survey of all the available data, Heeschen[10] later arrived at a value of 10^{60} ergs in agreement with the earlier value deduced from the electrical discharge theory.

GEOPHYSICS

Backscattering from the Upper Atmosphere (75–160 km) detected by Optical Radar

An optical radar system has recently been used to detect and study backscattering from the upper atmosphere (75–160 km). Although a much more detailed investigation is in progress, our preliminary results seem to indicate rough agreement with those of Fiocco and Smullin[1]. These authors suggested micrometeorites as a source of the echoes. When observations were made for brief time intervals (0·5 h or less), peaks were sometimes observed in the return-signal profiles. It should be noted, however, that when averaged over a period of several

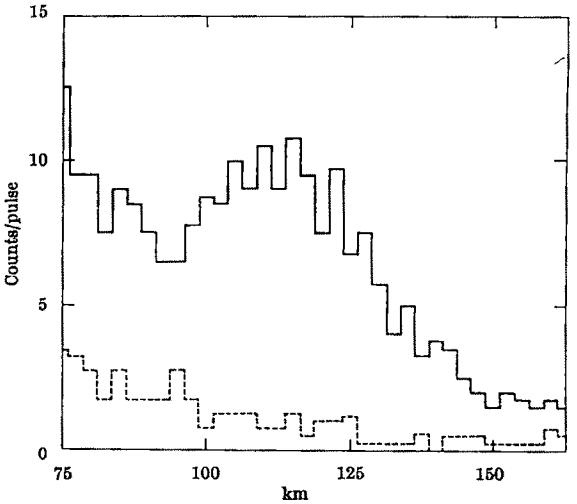

Fig.1. October 29, 1965, 07h 30m—08h 00m U.T. —, Observed return (average of ten laser pulses); – – –, background (average of ten laser pulses)

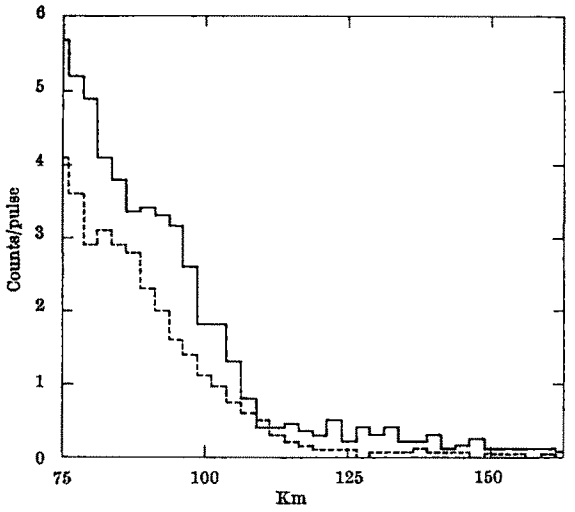

Fig. 2. October 31, 1965, 05h 30m - 09h 30m U.T. ——, Observed return (average of one hundred laser pulses); – – –, background (average of twenty laser pulses). (Note change of vertical scale from that of Fig. 1)

hours the return signal tends to become relatively smooth. It would seem, therefore, that the altitudes of the scattering layers, if they exist, fluctuate rapidly with time. The total scattering cross-section at 6943 Å observed by us is of the same order of magnitude as that reported by Fiocco and Colombo[2] ($\overline{N\sigma} \approx 10^{-12}$ cm^{-1}).

The optical radar consists of a Korad *K*-2*Q* ruby laser which is capable of producing single pulses containing 6–10 J at 6943 Å with a width of 10 nsec and a beam divergence of no more than 10 milliradians. The ruby is 8 in. long, 5/8 in. in diameter and is surrounded by a helical flash lamp. *Q*-spoiling is achieved by means of a Kerr cell. The laser pulse is brought to a focus at a 1/8 in. diameter aperture in a rotating mirror. The aperture is located in the focal plane of the University of Maryland's 20-in. reflector, which is a Broken Cassegrain with a 300-in. effective focal length. The beam divergence of the light leaving the telescope is less than 0·4 milliradians. In order to prevent air breakdown, the rotating mirror is installed in a chamber which is evacuated to a pressure of about 10μ mercury. An average energy of 1·0 J per pulse was sent into the atmosphere. Each laser pulse was monitored for proper firing time and for pulse amplitude. The return signal from the telescope is reflected by the rotating mirror to the cathode of a cooled E.M.I. 9558*A* photomultiplier tube (*S*-20 cathode) which is gated off during the actual laser firing. A 10 Å pass-band interference filter was used in the experiment.

Due to the small magnitude of the signal, the experiment consists of counting individual photoelectrons. The pulses are processed by Chronetics Nanologic Modules and sent through logic circuits[3] to an 'on-line' *CDC* 160 computer which is programmed[3] to store the counts from each altitude interval. At present the system is capable of obtaining an atmospheric scattering profile, for each laser pulse, with an altitude resolution of 2·5 km.

All measurements were made at College Park, Maryland (76° 57′ W. long., 39° N. lat.), while looking at the zenith. Figs. 1 and 2 give the results for two nights out of five for which we have obtained data. Fig. 1 shows the result of a series of shots taken during a short time interval. The scattering appears to be enhanced over the altitude ranges from 100 to 125 km. The total number of counts received (in 10 pulses) from 75 to 150 km was 2,240. The background was 350 counts. The number of photoelectrons due to backscattering is thus 1,890 with a mean error of 51 due to statistical uncertainty. Fig. 2 is the average of 100 laser pulses, over a period of 4 h, on a different night. The magnitude of the return signal is much lower than in Fig. 1 and no peaks are present. For the range 75–150 km we have: a total return of 5,070 counts, a background of 3,330 counts, a backscattering of 1,740 counts with a mean error of 147 counts. The high background is due to the fact that we use the same optical path for both transmitting and receiving. It is difficult to shield the phototube completely from the high light-levels present and from ruby fluorescence. Background measurements were made, during observations, by placing a black cloth over the end of the telescope tube.

We thank Prof. S. F. Singer for his encouragement and advice. This work was supported, in part, by the U.S. Weather Bureau under grant *WBG–4–FY–64*, A.R.P.A. grant *SD–101*, National Aeronautics and Space Administration grant *NGR* 21–002–022 and Bureau of Ships contract *NObsr* 72710.

PHYSICS

Surface Entrainment of Air by a Water Jet

This communication reports an investigation of the conditions for air entrainment when a water jet impinges normally on an air–water surface. The calculated critical entrainment velocity of the jet is compared with experimental values.

The surface profile of a deep liquid into which a perpendicular jet of the same liquid is falling can be deduced by considering the surface tension and the pressure on the surface caused by air entrained by the descending jet. Surface tension will cause a meniscus to form between the liquid surface and the jet. The angles of contact will be zero, so the meniscus will have the usual form:

$$y^2 = \frac{2\sigma}{g\rho_L}(1 - \cos\psi)^* \qquad (1)$$

The equation is, however, more manageable in cylindrical co-ordinates about the axis of the jet. The transformation is straightforward but tedious, and yields:

$$r - r_0 = A\left[\tfrac{1}{2}\log_e\left\{\frac{1+\sqrt{1-\frac{y_2}{4A^2}}}{1-\sqrt{1-\frac{y^2}{4A^2}}}\right\} + 0{\cdot}5329 - 2\sqrt{1-\frac{y^2}{4A^2}}\right] \qquad (2)$$

where:

$$A^2 = \frac{\sigma}{g\rho_L}$$

The liquid jet, as it travels between the nozzle and the surface, will cause the air alongside to be accelerated. This air will strike the surface of the liquid causing a depression of the meniscus.

It is assumed that the viscous flow of air dragged by the jet is laminar, and no pressure variations occur. The velocity of the air parallel to the jet is U, and is a function of the radius of the jet and the height through which the jet has fallen.

Consider an infinitesimal annulus of air at radius r, radial increment δr, and height δy. The mass of the

annulus is $2\pi r\delta y\delta r\rho_A$ and the net viscous force acting on the annulus is:

$$-2\pi r\delta y\eta\frac{\partial U}{\partial r}\delta r,$$

$\frac{\partial U}{\partial r}$ being negative. Therefore, the acceleration of the annulus is given by:

$$\frac{\partial U}{\partial t}=\frac{\text{Force}}{\text{Mass}}=\frac{\eta}{\rho_A}\frac{\partial U}{\partial r} \qquad (3)$$

r and t are independent variables, so the partial differential equation is easily soluble.

$$\frac{\partial U}{\partial t}=-\frac{\eta}{\rho_A}\frac{\partial U}{\partial r}=K$$

Therefore:

$$U=Kt-\frac{\rho_A}{\eta}Kr+L \qquad (4)$$

where K and L are constants.

It is now assumed that the jet is a cylinder of radius r_0. The effect of this approximation on the air flow will be small if the flow is laminar.

The constants can be obtained from the boundary condition that at the surface of the cylinder $r=r_0$ and

$$U=V=V_0+gt$$

Substituting this condition into equation (4):

$$V_0+gt=Kt-\frac{\rho_A}{\eta}Kr_0+L$$

and, by equating the coefficients of powers of t,

$$K=g$$

and

$$L=V_0+\frac{\rho_A Kr_0}{\eta}=V_0+\frac{\rho_A gr_0}{\eta}$$

Therefore:

$$U=V_0+gt-\frac{\rho_A g}{\eta}(r-r_0) \qquad (5)$$

At the liquid surface:

$$V_0+gt=V_L$$

and so:

$$U=V_L-\frac{\rho_A g(r-r_0)}{\eta} \qquad (6)$$

The air incident on the surface causes a pressure equal to the rate of change of momentum per unit area

$$P=\rho_A U^2=\rho_A\left\{V_L-\frac{\rho_A g(r-r_0)}{\eta}\right\}^2$$

The air pressure P will cause a depression of the surface equal to:

$$y=\frac{\rho_A}{g\rho_L}\left\{V_L-\frac{g\rho_A}{\eta}(r-r_0)\right\}^2 \qquad (7)$$

Fig. 1 shows the surface tension curve for water and the air pressure curve for values of $V_L=200$, 300 and 400 cm/sec. The resultant surface profiles, the sums of these graphs, have been plotted. For $V_L=300$ or 400 cm/sec a maximum is present in the resultant surface which is unstable and will collapse to $y<0$, leaving a depression, with consequent air entrainment. A point of inflexion, in fact, occurs for $V_L=231$ cm/sec, and above this critical velocity air could be carried into the body of the liquid.

The formation of surface-entrained air bubbles was investigated experimentally, and it was found that a critical velocity for air entrainment did exist but varied with jet diameter. The results are shown in Fig. 2. As the jet diameter is reduced, the critical velocity approaches an asymptote at about 235 cm/sec. This asymptote agrees well with the predicted value.

It has been assumed in the analysis that the airflow is laminar. The Reynolds's number of the airflow will be approximately equal to that of a solid circular jet of air of the same velocity and diameter as the jet of water. This is because at any specific time the annulus of air

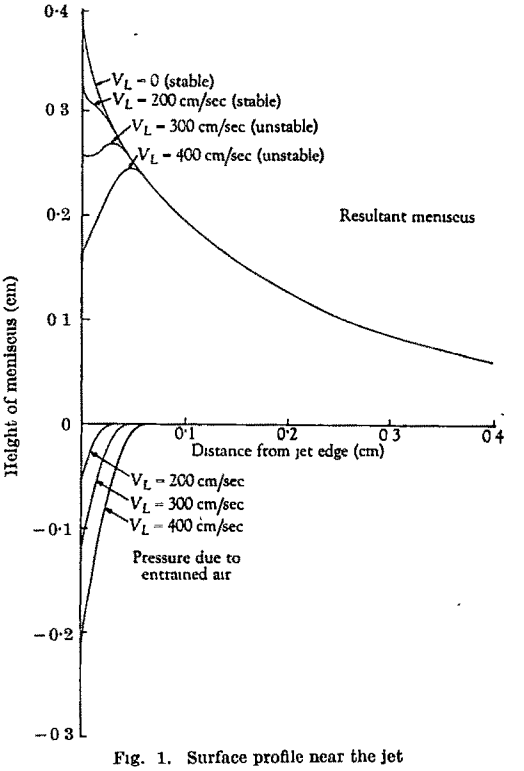

Fig. 1. Surface profile near the jet

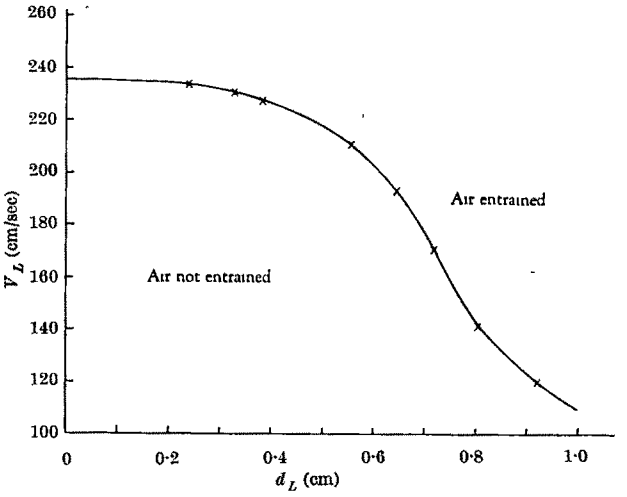

Fig. 2. Variation of critical entrainment velocity with jet diameter

will be influenced equally by an air or a water core. The Reynolds's number of the airflow when the critical velocity starts to fall (Fig. 2) is about 600 at $d_L=0{\cdot}4$ cm. The decrease of critical velocity as d_L increases is therefore probably due to the airflow becoming turbulent, as Streeter[1] quotes the transition region for a circular jet as being approximately defined by $300\leqslant N_R\leqslant 1{,}000$.

Resolution in Low-angle Electron Diffraction

THE optical system of a high performance electron microscope can also be used for investigations other than simple transmission microscopy. One such 'unconventional' application is low-angle electron diffraction. This technique was introduced by Mahl and Weitsch[1] and has since been used in various investigations of structure[2–4]. Its advantage, as compared with X-ray low-angle diffraction, lies in the higher resolution which it offers, the much shorter exposure times required, and the possibility of making visible the area contributing to the diffraction pattern.

In the course of our investigations we became interested in the attainable resolution in connexion with various arrangements of the optical system. The resolution of the system can be defined by the number n given by the relation[5]:

$$n = \frac{r_F}{L} = \frac{r_F}{l_D M} \qquad (1)$$

where r_F is the radius of the primary spot on the photographic material, L is the effective camera length, l_D is the distance of the specimen from the object plane of the intermediate (eventually, projector) lens, and M is the magnification of the projector system.

The resolution of an optical system consisting of a Tesla *BS* 413 electron microscope equipped with a double condenser lens, an intermediate lens and a projector lens was investigated. The specimen was placed in its normal position and the objective lens was not energized. The first condenser lens was highly excited in order to produce a demagnified image of the cross-over and this image was focused by means of the second condenser lens, onto the object plane of the intermediate lens. The diffraction pattern in the object plane was then magnified and projected onto the photographic material by means of the projector system. The excitation of the intermediate lens could be chosen so as to operate it as a magnifying or reducing lens; eventually the intermediate lens could be switched off so that the diffraction pattern focused by the second condenser lens onto the object plane of the projector lens was magnified only in one stage.

The dependence of the resolution number n on the diffraction distance l_D (and hence on the way of operation) is given in Fig. 1 for three focal lengths f_E of the first condenser lens. The diameter of the cross-over is supposed to be 40μ. The left-hand side of the graphs (10 mm $\leqq l_D \leqq$ 180 mm) accounts for the intermediate lens functioning as a magnifying lens, the right-hand side (300 mm $\leqq l_D \leqq$ 1,500 mm) holds for the intermediate lens functioning as a reducing lens[6]. It is evident, from the optical point of view, that the resolution was higher for the intermediate lens operated as a reducing lens and, in fact, approached that of the best diffraction cameras. In practice, it is advantageous to use only the projector lens for magnification of the diffraction pattern (in Fig. 1, $l_D = 300$ mm) because the working parameters can be more easily reproduced and the resolution remains very high.

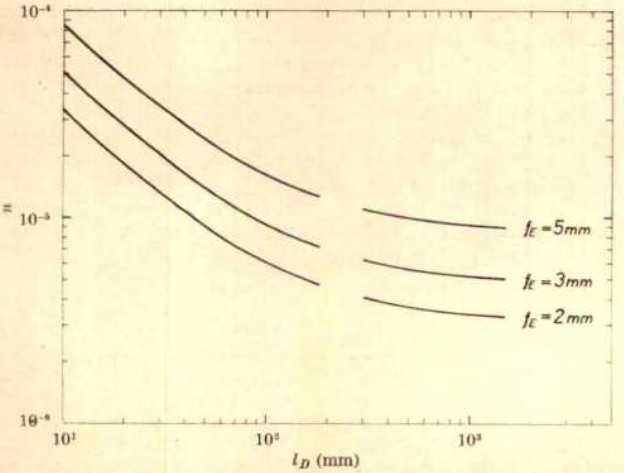

Fig. 1. Computed resolution number, n, for three focal lengths of the first condenser lens against diffraction length, l_D, characterizing different ways of operation of the projection system (excitation of the projector lens was kept constant)

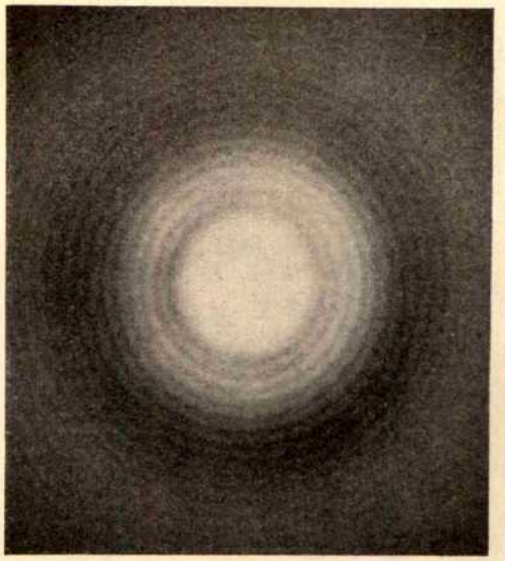

Fig. 2. Low-angle diffraction pattern of a random assembly of polystyrene latex spheres 4130 ± 80 Å

The largest observable spacing can be obtained from the Bragg equation:

$$2d \sin\theta = 2d\theta = \lambda \qquad (2)$$

where d is the spacing characterized by the Laue indices (h, k, l), θ is the Bragg angle, λ is the wave-length.

We can substitute $n = 2\theta$ in the equation (2) and thus obtain a relation for the theoretically largest observable spacing in form:

$$d_t = \frac{\lambda}{n} \qquad (3)$$

The introduction of the specimen results in an enlargement of the primary spot. If we suppose in our conditions that the real diameter of the primary spot is about twice the theoretical value, then we can write for the largest observable spacing:

$$d \approx \frac{\lambda}{2n} \qquad (4)$$

To test experimentally the validity of relation (4) we used spheres of monodisperse polystyrene latex. It can be shown[6] that the mean diameter of the spheres can be considered to be practically equivalent to the Bragg spacing d, because the difference of scattering angle belonging to successive secondary maxima corresponds closely to the angle 2θ in the equation (2).

An example of the pictures taken during the tests is given in Fig. 2. It shows the diffraction pattern of a random assembly of latex particles 4,180 ± 80 Å in diameter obtained under the following experimental conditions: $\lambda = 4{\cdot}33 \times 10^{-2}$ Å ($u^* = 75$ kV), $f_E = 2{\cdot}5$ mm, $l_D = 300$ mm (the intermediate lens was not energized), $L = 35{\cdot}7$ m, $2r_F = 3{\cdot}6 \times 10^{-1}$ mm. The resolution number, n, according to equation (1), was 5×10^{-6}, and the theoretically largest observable spacing, d_t, was 8·600 Å. If we consider the enlargement of the primary spot by the presence of the specimen, the observable spacing, d, from equation (4) is 4·300 Å. Clearly resolved higher secondary maxima in Fig. 2 show that, from the optical point of view, observation of spacing given by equation (4) is possible. The aforementioned calculations and experiments were performed with the assumption that a normal hairpin filament

was being used in the electron gun. The use of a point cathode (and hence a lower value of the primary spot diameter, $2r_F$) results in a still higher resolution than given in Fig. 1.

GEOCHEMISTRY

Ion Separation in Bursting Air Bubbles: an Explanation for the Irregular Ion Ratios in Atmospheric Precipitations

It is well known that a considerable part of the soluble salts present in soil, lakes and rivers is derived from rainwater[1]. There is little doubt that the salt content in the rainwater comes mainly from ocean water spray, which is carried into the atmosphere from the surface of the sea, where tiny droplets are formed by air jets shooting out of the top of bursting air bubbles[2].

Note: All sodium–potassium ratios are given in terms of Na^+/K^+ values, although in the literature quoted they are given as K^+/Na^+.

The reason why the salts, derived from such action, found in rainwater and snow, have ion ratios incompatible with the ratios found in ocean water has remained obscure. Although the Na^+/K^+ ratio in sea water is 27, it is always lower in precipitation (rain and snow), sometimes being as low as 2. The Cl^-/Br^- ratio in sea water is 302, but is always much lower in rainwater or snow, often less than 50, sometimes less than 20. Examples are given in Tables 1 and 2.

Explanations of these facts have so far not been very satisfactory, including the suggestions that they are brought about by the influence of terrestrial dust, by oxidation of halogens by ozone, by biological absorption of potassium in the ocean surface, or by fractionation crystallization in the atmosphere.

We propose here a mechanism for the separation of ions which becomes effective at the moment and shortly before the bursting of ocean water bubbles: in part this follows the suggestion made by Ken Sugawara and Nobuko Kawasaki[3] for Sr^{++}/Ca^{++} and Na^+/Cl^- separation. Such a mechanism would lead to a spray of droplets with ion ratios different from those of the ocean water from which it is derived. As the bubbles become thinner and thinner, a solution runs down the wall between the concave inner surface and the convex outside surface. There will be a tendency for the larger and generally heavier ions to stay in the skin[4], the smaller ones will run off with the solution. When the jet atomizes the bursting skin, the small droplets formed will be relatively rich in the larger ions. It is clear that this mechanism will be influenced by a number of factors, and will probably depend on initial concentrations and the radius of the bubbles. The jet might also disperse solution from the bottom of the bubble, thus admitting varying quantities of original solution to the fine top spray: this may somewhat obscure the effect.

We have carried out some preliminary investigations to test the hypothesis. Distilled water was prepared by boiling sea water, tap water and lake water at atmospheric pressure with and without the conventional spray trap. It can be seen from Table 3 that the spray was reduced through the conventional spray trap by an order of magnitude or more: however, the ratio of the ions, contained in the spray, differed essentially in the same way from the ratio of the ions in the original solution, and was independent of the efficiency of the trap. The variation of ratios caused by artificial distillation was similar to the variation experienced with sea water and rainwater in Nature.

Another series of experiments was undertaken with sea water as well as with artificial salt solutions at ambient temperature (20° C). In these experiments, instead of carrying out distillations, air was bubbled through the various solutions (every bubble was about 5 mm diameter) in a conventional gas washing flask instead of distillation. The air was filtered through cotton wool before and after it was passed through the salt solution. The salts absorbed by the cotton wool from the air were extracted with water, and the resulting solution was analysed. The cotton wool itself contained certain salts, and thus deductions were made for the amounts of Cl^- and Br^- or Na^+ and K^+ respectively—values having been obtained by extraction of the cotton wool with water (see Table 4*a*).

NaCl 30 g, $CaCl_2$ 3·4 g, 1	312	10	0·243	0·0453	5·4
NaCl 30 g, $CaCl_2$ 30 g, 1	312	1·1	0·206	0·382	0·54

Another artificial solution, containing magnesium and lead nitrate, was treated in the same way and the spray analysed. The cotton wool used for absorbing the spray contained magnesium to the extent of less than 0·024 mg/g cotton and lead to the extent of less than 0·005 mg/g cotton (see Table 4*a*).

In another series of experiments, the salts carried over by the air were absorbed in water that had been distilled three times. The original solutions were also prepared by dissolving the various salts in thrice-distilled water (see Table 4*b*).

It can be seen that an air stream with single bubbles shows the effect almost as markedly as the distillation at 100° C. An air stream where many bubbles coalesce to form a foam has practically no effect of ion separation. The fact that the spray of boiling solutions shows the separation of ions clearly indicates that no solid-phase separations occur during evaporation from droplets as suggested as a 'post-wave breaking fractionation' (Sugawara and Kawasaki[3]); the separation seems to occur only in the bursting bubble.

The change of ion ratios by 'syn-bubble breaking fractionation', as Sugawara and Kawasaki propose to call it, is probably of considerable importance in the accumulation of the heavy or large ions, such as potassium, found in arid soils in which rainwater has been evaporated to dryness for a long time, without the residue being washed out. The way in which heavy metals accumulate in latterites may also be related to the ion separation in breaking bubbles.

The analytical procedures used in these investigations were as follows:

Cl^- (Br^-) —mercurimetric method.

Br^- —modified Van der Meulen method (Kaplan and Schnerb[5]).

K^+ and Na^+—flame-photometric method.

Mg^{++} —complexometric (EDTA) method.

Pb^{++} —colorimetric method, according to *British Pharmacopoeia*.

Ca^{++} —flame-photometric method.

We thank Miss C. Halevy for her help with the analytical work.

CHEMISTRY

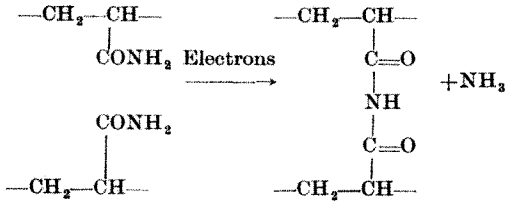
Collapse of Polyacrylamide Molecules on Electron Irradiation

Individual spherical molecules of glassy amorphous polymers, with molecular weights of more than about 5×10^5, can be deposited from a solvent-precipitant mixture, on to a thin substrate and observed in the electron microscope after shadowing with a heavy metal[1,2].

It has been reported that molecules of polyacrylamide behave in an unusual way when examined in the electron microscope[2]. The molecules appear to collapse into a shapeless mass, even in a weak electron beam, and even though the glass transition temperature of polyacrylamide is of the order of 130° C. The behaviour is similar to that of molecules of rubbery polymers, which are not self-supporting. Richardson[2] has suggested that this effect may represent some inherent weakness of this type of polymer structure to electron irradiation.

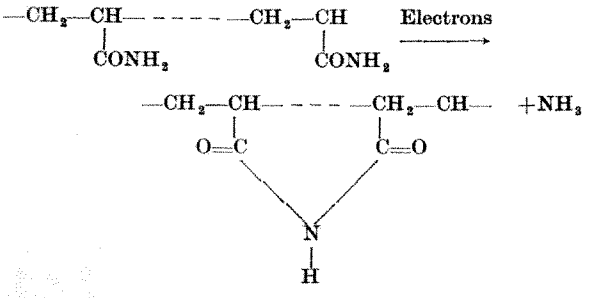
The observation has been confirmed and the effect investigated experimentally by subjecting the bulk polymer to electron irradiation. Results suggest that the phenomenon is due to intramolecular bond formation rather than to degradation of the polymer.

Particles of polyacrylamide weighing about 15×10^{-5} g were subjected to electron bombardment in an A.E.I. *E.M. 6G.* electron microscope, using electron energies of 30–100 kV, electron currents of 15–70 μamp and exposure times of 5–100 sec. The particles were then examined visually under a low-power optical microscope and a solubility test was carried out.



It was found that the polymer quickly became insoluble after even short exposures to a weak electron beam (for example, 10-sec exposure in an electron beam of 15 μamp). Water is the best solvent for polyacrylamide, and a 10^{-3} per cent solution of non-irradiated polymer can be obtained in about 3 h without agitation, while the irradiated polymer readily swells to several times its original volume, but remains quite insoluble after immersion in water for 10 days.

After short exposure times to weak electron beams, the polymer does not change visually, except for a decrease in volume of about 10 per cent, which was observed in the electron microscope. The polymer particles remain transparent, colourless, and identical with the non-irradiated polymer. After long exposures, the polymer becomes faintly yellow in colour, but still remains transparent. The yellowing becomes more pronounced as the exposure time and/or intensity is increased, and finally it becomes opaque. As the exposure conditions become more severe, an accompanying decrease in solvent swelling occurs.



Using a simple indentation test, no difference in mechanical behaviour was detected between the irradiated and

non-irradiated polymer. Softening commenced at 130 ± 5° C in both cases.

These observations strongly indicate that intermolecular cross-links are formed, on electron irradiation, rather than that the polymer is degraded. It is proposed that the following imidization occurs:

The collapse of single molecules of polyacrylamide in an electron beam may be explained on the basis of intramolecular imidization. The molecules are sprayed from a solvent–precipitant mixture in which the solvent is more volatile than the precipitant. On evaporation, the solvent becomes progressively poor and conditions for polymer–polymer contacts become highly favourable. Spherical, self-supporting molecules can be isolated if the solution is sufficiently dilute. Each molecule consists of a tightly and randomly coiled chain. In this conformation, amide groups along the chain will be in close proximity to one another, and favourable conditions will exist for the condensation of neighbouring amide groups on electron irradiation, as follows:

Further experiments are planned, in an effort to confirm cross-linking. The relationship between irradiation conditions and degree of cross-linking will be investigated from solvent swelling measurements.

Thanks are due to the American Cyanamid Co. for a donation of polyacrylamide.

Electron-transfer Reactions of Europium (II) in Aqueous Perchloric Acid Solutions

Electron-transfer reactions with europium (II) as the reducing ion have been studied in aqueous perchloric acid solution, $\mu = 2{\cdot}0$ M, using conventional spectrophotometric techniques. Such reactions are of interest in that little is known about the readiness with which electrons are transferred to and from *f*-orbitals[1,2]. Although europium (II) is the most stable of lanthanide (II) oxidation states, it reacts rapidly with oxygen and oxygen-free systems have therefore to be used. In preliminary experiments it was shown that europium (II) reduction of perchlorate ions is negligible (europium (II) concentrations of the order 0·04 M).

The reaction

$$Eu^{II} + V^{III} \rightarrow Eu^{III} + V^{II}$$

is first order in both the reactants

$$\text{Rate} = k_{obs}[Eu^{II}][V^{III}]$$

where k_{obs} is hydrogen-ion dependent

$$k_{obs} = k_1 + k'[H^+]^{-1}$$

The rate constant k_1 (0·0090 l.mole^{-1}sec^{-1} at 25° C) corresponds to the reaction of Eu^{2+} with V^{3+}, and it is assumed that k' is for the reaction of Eu^{2+} with VOH^{2+}. Thus k' may be written k_2K_H, where k_2 (2·00 l.mole^{-1}sec^{-1} at 25° C) is the true rate constant and K_H (0·002 l.$^{-1}$mole) (ref. 3) the hydrolysis constant for V^{3+}. From the temperature-dependence activation parameters corresponding to k_1 and k_2 are $\Delta H_1^{\ddagger} = 11{\cdot}4$ kcal mole^{-1}, $\Delta S_1^{\ddagger} = -30{\cdot}1$ e.u., $\Delta H_2^{\ddagger} = 6{\cdot}2$ kcal mole^{-1} and $\Delta S_1^{\ddagger} \sim -35$ e.u. Rates observed for the reaction of chromium (II) with vanadium (III) ($k_{obs} = 0{\cdot}85$ l.mole^{-1}sec^{-1} in 1·0 N, $HClO_4$ at 25° C, $\mu = 2{\cdot}0$ M) (ref. 4) are considerably faster than those for the europium (II) reaction ($k_{obs} = 0{\cdot}013$ l.mole^{-1}sec^{-1} under identical conditions) although the free energy change is slightly less favourable.

From the difference in standard oxidation potentials of 0·02 volts for the Eu^{II}/Eu^{III} and Cr^{II}/Cr^{III} couples[5] an equilibrium constant of 2·2 can be calculated for the reaction:

$$Eu^{II} + Cr^{III} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} Eu^{III} + Cr^{II}$$

Since the exact nature of the solution medium is important, and the difference in standard oxidation potentials is so very small, such an equilibrium constant can be considered only approximate. Both the forward and reverse reactions have been studied and are extremely slow at 25° C ($k_3 \sim 1{\cdot}7 \times 10^{-5}$ l.mole^{-1}sec^{-1} and $k_4 \sim 1{\cdot}4 \times 10^{-5}$ l.mole^{-1} sec^{-1}). The addition of chloride ions does not affect the forward reaction, but in the reverse the rate is much faster and substitution inert $CrCl^{2+}$ is formed. With $CrCl^{2+}$ as the chromium (III) reactant the forward reaction is also much faster:

$$Eu^{2+} + CrCl^{2+} \xrightarrow{k_5} Eu^{3+} + Cr^{2+} + Cl^-$$

and at 25° C $k_5 = 2{\cdot}2 \times 10^{-3}$ l.mole^{-1}sec^{-1}. A comparison of rate constants for the reactions $Eu^{2+} - EuCl^{2+}$ (ref. 6), $Fe^{2+} - FeCl^{2+}$ (ref. 7), $Cr^{2+} - CrCl^{2+}$ (ref. 8), and $Eu^{2+} - CrCl^{2+}$ (which have little or no free energy change) and for the reactions $Cr^{2+} - Co(NH_3)_5\ Cl^{2+}$ and $Eu^{2+} - Co(NH_3)_5\ Cl^{2+}$ (ref. 2) (which have almost identical free energy change) supports the belief that it is more difficult to transfer electrons from *f*-orbitals.

The reaction

$$Eu^{II} + V^{IV} \xrightarrow{k_6} Eu^{III} + V^{III}$$

is too fast for a full kinetic study using conventional techniques. At 0° C with reactant concentrations $\sim 10^{-4}$ M ($\varepsilon = 530$ for Eu^{II} at 320 mμ) and $[H^+] = 0{\cdot}2$ N, k_6 is $\sim 10^3$ l.mole^{-1}sec^{-1}. In the reactions of europium (II) with chromium (III), vanadium (III), vanadium (IV) and iron (III) (from ref. 9) there is a rough linear correlation of rate constants with the standard free energy change.

BIOCHEMISTRY

Action of Neuraminidase on Human Kidney Alkaline Phosphatase

STARCH-GEL electrophoresis and chromatography on substituted cellulose ion-exchangers have demonstrated that extracts of human kidney contain more than one protein possessing alkaline phosphatase activity. Similar patterns of distribution of enzymatically active zones after starch-gel electrophoresis have been obtained by several workers[1,2] and three distinct zones can often be demonstrated: a single zone migrating rapidly towards the anode (Fig. 1, zone 1), a second broad, heterogeneous component (Fig. 1, zone 2), and a third band which migrates very slowly and which may represent enzyme bound to lipid material (Fig. 1, zone 3). The first rapidly migrating component cannot be demonstrated in all extracts, but may sometimes appear after storage at −15° for some months. Elution patterns of kidney alkaline phosphatase from DEAE-'Sephadex' columns exhibit a broad similarity, but here also there is some variation from extract to extract. A common feature of all such chromatograms, however, is a sharp peak of activity appearing first in the effluent (Fig. 2). The elution pattern of the remaining enzyme is more varied, but often a second fairly broad peak is obtained[3]. The presence of sialic acid groups is known to increase the electrophoretic mobility of proteins[4], and Robinson and Pierce[5] have demonstrated that, after treatment with neuraminidase to remove sialic acid, the electrophoretic mobility of certain alkaline phosphatase components was reduced. To investigate whether the binding of sialic acid is in any way related to the heterogeneity of kidney alkaline phosphatase, this enzyme has been treated with neuraminidase.

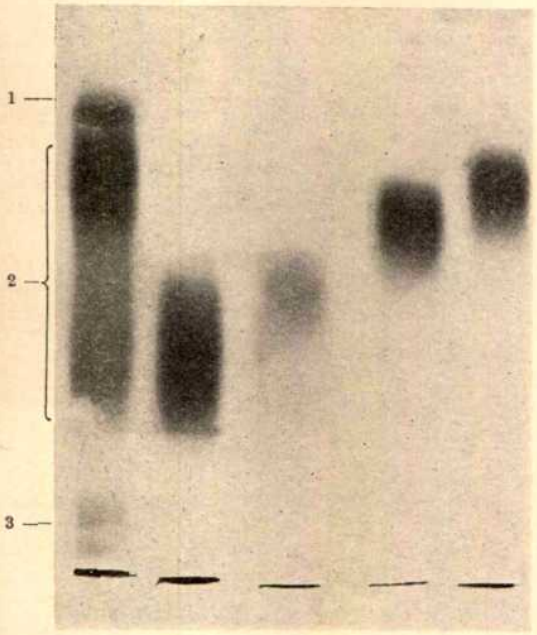

Fig. 1. Starch-gel electrophoresis of alkaline phosphatase of human kidney extract (*e*), and fractions (*A*–*D*) from DEAE-'Sephadex' column. Numbers indicate active zones in whole extract; letters correspond with chromatographic fractions of Fig. 2. (Anode at top, sample slots near bottom)

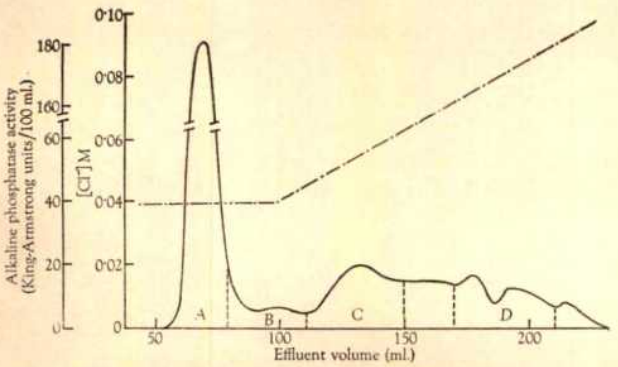

Fig. 2. Chromatogram of kidney extract on DEAE-'Sephadex' column. ———, Phosphatase activity; – – –, chloride concentration

Extracts of alkaline phosphatase were made by Morton's[6] butanol method from human kidneys obtained from the post-mortem room within a few hours of death. The crude extracts were concentrated by dialysis against a 30 per cent 'Carbowax' solution and partially purified by chromatography on DEAE-'Sephadex'. The enzyme was eluted by an increasing chloride ion concentration in *tris* buffer[5] and 5 ml. fractions were collected. Each fraction was assayed for phosphatase activity and chloride concentration, and fractions coinciding with peaks of enzyme activity were concentrated prior to electrophoresis on starch gel. Horizontal starch-gel electrophoresis was carried out in the discontinuous buffer system of Poulik[7] at *p*H 8·6 for 17 h at 10 V per cm and zones of enzyme activity were then located by the method of Estborn[8]. Kidney alkaline phosphatase extract (0·1 ml.) or concentrated column effluent fractions were incubated at 37° in 0·4 ml. of *tris* buffer (*p*H 7·7) with 50 U. neuraminidase (L. Light and Co.) for 20 h (ref. 5).

Fig. 2 shows a chromatogram of kidney alkaline phosphatase on DEAE-'Sephadex' and Fig. 1 the electrophoretic mobilities on starch gel of the various kidney phosphatase components eluted from the column. The first peak of the chromatogram corresponds with the most cathodal portion of the second electrophoretic band and it appears electrophoretically homogeneous. Alkaline phosphatase that elutes at progressively higher chloride ion concentrations consists of further portions of the second band of increasing electrophoretic mobility. Electrophoresis of all fractions demonstrated that the original pattern obtained with whole kidney extract could be built up. Re-chromatography of individual fractions followed by electrophoresis showed that their relative mobilities remained unchanged.

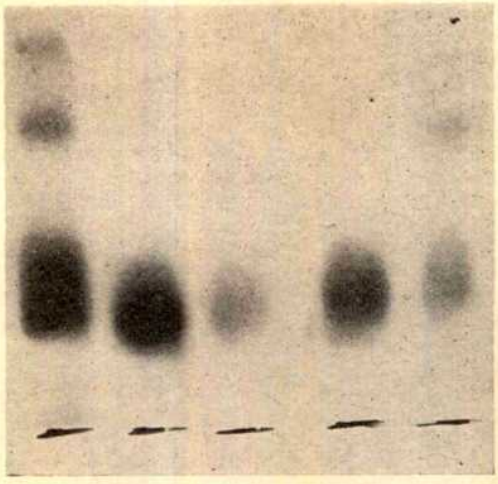

Fig. 3. Starch-gel electrophoresis of alkaline phosphatase of kidney extract (*e*) and column fractions (*A*–*D*) after neuraminidase treatment. (Anode at top, sample slots near bottom)

Fig. 3 shows the effect of treatment with neuraminidase on the electrophoretic distribution of whole kidney alkaline phosphatase and on the several chromatographic fractions. With both the whole extract and the chromatographic fractions, the main product of such treatment was a slowly migrating component, and a comparison of the

electropherograms showed that the slowly migrating enzyme species produced from each were electrophoretically identical. There was no significant loss in enzyme activity. Faster-migrating zones of low activity could be demonstrated in the kidney extract and in the last chromatographic fraction, *D*. These may indicate the presence of neuraminidase-resistant components in kidney alkaline phosphatase or they may arise from incomplete action of neuraminidase. Some evidence for the latter possibility was obtained by prolonging the time of incubation with neuraminidase when the remaining faster bands became more diffuse and weaker in activity.

The heterogeneity of the chromatograms and electropherograms of kidney alkaline phosphatase might suggest that there is in this organ more than one protein with alkaline phosphatase activity and that the several proteins are structurally different. However, as the results of chromatographic and electrophoretic separation procedures with different tissue preparations are not always identical, it is possible that there is only one kidney alkaline phosphatase, perhaps represented by the first chromatographic peak since this is the component which occurs most reproducibly, from which other enzymatically active forms may be derived. The present experiments would seem to indicate that the structurally different, but functionally similar, alkaline phosphatases of human kidney arise as a result of variations in the amount of bound sialic acid. Removal of varying amounts of sialic acid during the extraction and isolation procedure may give rise to the variation between chromatograms of different extracts. Boyer[1] has demonstrated that kidney alkaline phosphatase exists in two immunologically distinct forms, so that it would seem that the action of neuraminidase can alter the antigenic properties as well as the electrophoretic mobility of kidney alkaline phosphatase. The question of whether differences in the amount of sialic acid bound by the enzyme exist in the cell, so giving rise to several forms of the enzyme *in vivo*, or whether they are artefacts produced in the laboratory from a single enzyme species, has still to be answered.

Separation of Serum 5′-Nucleotidase and Non-specific Alkaline Phosphatase Activities

Phosphatases which exhibit a high specificity for the hydrolysis of nucleoside-5′-phosphates (5′-nucleotidases[1]) usually occur in association with non-specific alkaline phosphatases, for example, in blood serum. Methods which have been used for the estimation of the relative activities of the two enzymes in serum have depended on comparison of the rates of hydrolysis of two different phosphate substrates[2], or on the specific inhibition of 5′-nucleotidase by nickel ions[3]; few attempts have been made to separate the two types of enzyme activity[5]. This communication describes the resolution of the 5′-nucleotidase and alkaline phosphatase activities of human blood serum by ion-exchange chromatography and gel-filtration.

Sera from patients with obstructive biliary disease, in which both types of enzyme activity are greatly increased, were used as the source of the enzymes. Chromatography on DEAE-cellulose was carried out in 0·05 M *tris*-HCl buffer (*p*H 7·7)—the elution being by means of a gradient of increasing chloride concentration; the serum sample was dialysed overnight against the starting buffer before application to the column. Gel-filtration was carried out in 0·9 per cent w/v sodium chloride solution on a column of 'Sephadex' *G*-200 (Pharmacia, *AB*, Uppsala, Sweden). In each case the effluent fractions (3 ml.) were tested for alkaline phosphatase activity by the method of Kind and King[4] and 5′-nucleotidase activity by the method of Campbell[2]. In both types of experiment the recoveries of 5′-nucleotidase and alkaline phosphatase were between 80 and 100 per cent. The results are shown in Figs. 1 and 2. Ion-exchange chromatography shows that the greater part of the 5′-nucleotidase activity elutes at a higher chloride concentration than the bulk of the alkaline phosphatase (Fig. 1). Both enzymes are to some extent heterogeneous, and each major peak contains residual amounts of the other type of activity. It is probable that these contaminants represent portions of the different enzymes eluting at the same chloride concentrations rather than a lack of specificity in the enzyme assays: 5′-nucleotidase from other sources has been shown to have negligible action on phenyl phosphate, the substrate used for alkaline phosphatase assays, while the nickel-inhibited hydrolysis of adenylic acid, the method used to estimate 5′-nucleotidase[3], is highly specific for this enzyme. On gel-filtration, most of the 5′-nucleotidase activity is completely excluded from the gel (Fig. 2), while alkaline phosphatase elutes as a fairly symmetrical peak in the 7*S* globulin region. As on ion-exchange chromatography, the 5′-nucleotidase is heterogeneous on gel-filtration.

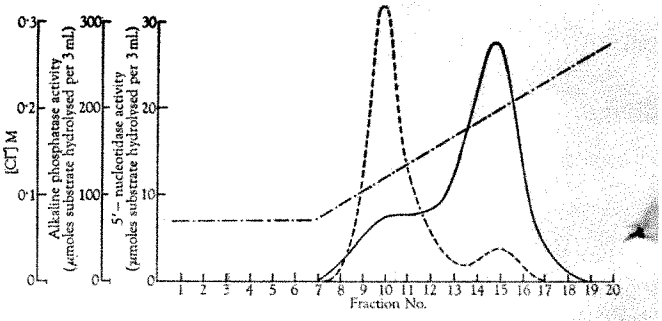

Fig. 1. Chromatogram of serum (1 ml.) on DEAE-cellulose column (28 × 1 cm). ———, 5′-Nucleotidase activity; – – –, alkaline phosphatase activity; ——·——, chloride concentration. Fraction volumes, 3 ml. each

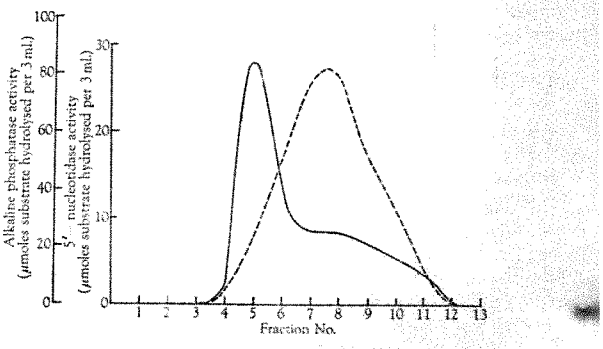

Fig. 2. Gel-filtration of serum (1 ml.) on 'Sephadex' *G*-200 column (32 × 1·3 cm). ———, 5′-Nucleotidase activity; – – –, alkaline phosphatase activity. Fraction volumes, 3 ml. each

The gel-filtration behaviour of the major part of the 5′-nucleotidase activity suggests that this enzyme may be of high molecular weight, an inference compatible with the observation of Kowlessar, Pert, Haeffner and Sleisenger[5] that 5′-nucleotidase is found in the β-lipoprotein and slow α_2-globulin regions after starch-gel electrophoresis of serum at *p*H 9. However, the combination of considerable negative charge at *p*H 7·7, as shown by the higher chloride ion concentrations required to elute 5′-nucleotidase from DEAE-cellulose, with apparently large molecular size may indicate the presence in the molecule of a carbohydrate component, since carbohydrate-containing proteins may behave anomalously on gel-filtration.

These methods for the separation of serum alkaline phosphatase and 5′-nucleotidase confirm the distinct identities of these enzymes, and provide a basis for the further purification and study of the latter.

Isolation of γ-Hydroxynorvaline from *Lathyrus odoratus* Seed

In the course of an investigation of the metabolic pathways responsible for the incorporation of ^{14}C-cyanide into the amino-acids of young seedlings[1], paper chromatographic methods indicated that a previously unrecognized amino-acid was present in low concentration in extracts of *Lathyrus odoratus* (sweet pea) seedlings. This amino-acid has now been shown to be γ-hydroxynorvaline (I, α-amino-γ-hydroxypentanoic acid). The hydroxyamino acid first appears as a brown-coloured spot on chromatograms treated with ninhydrin, but the colour changes rapidly to the more usual blue-purple characteristic of most amino-acids.

γ-Hydroxynorvaline is present also in dry sweet pea seed and this material has provided a source for isolation. Ground seed (15 kg) was extracted twice with 75 per cent (v/v) ethanol (60 l.) during a period of 4 weeks. The extract obtained after pressing and filtering was applied to a column containing 8 kg of 'Zeo-Karb 225' resin (H^+ form) to absorb amino-acids. After non-cationic substances had been removed by thorough washing, the amino-acids were recovered by elution with 2 N ammonia. The eluate was evaporated to dryness and the residue was re-dissolved in water (1·5 l.) and adjusted to *p*H 4·5. This solution was applied to a column of 'Dowex-50 *W*' (× 8, mesh 100–200, length 75 cm, diam. 15·5 cm) and, after washing with 10 l. of water, the amino-acids were fractionated by elution with 0·25 N ammonia. Early fractions (each of 50 ml.) contained large amounts of γ-glutamyl-β-aminopropionitrile (*Lathyrus* factor)[2] in addition to small quantities of aspartic and glutamic acids: 40 g of pure γ-glutamyl-β-aminopropionitrile was obtained from these pooled fractions. γ-Hydroxynorvaline was present in two groups of fractions: first in fractions with alanine, serine and some other neutral amino-acids eluted after γ-glutamyl-β-aminopropionitrile, and then in the last ten of 104 fractions collected in all. In most of those later fractions the hydroxyamino acid was mixed with basic amino-acids, but the last three fractions contained only γ-hydroxynorvaline. After crystallization from aqueous-acetone, pure γ-hydroxynorvaline (200 mg) was obtained from the solid present in these three fractions.

The elution of γ-hydroxynorvaline at two points during the fractionation can be explained by lactonization of a proportion of the γ-hydroxyamino acid under the influence of H^+ ions liberated during amino-acid absorption on the cation-exchange resins. Molecules existing in the lactone form are basic and consequently are eluted together with, or later than, the basic amino-acids.

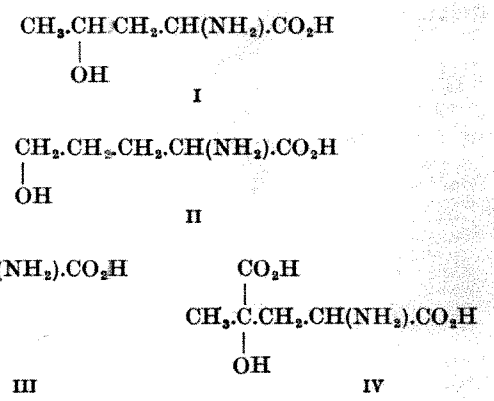

Table 1. The R_F values of γ-hydroxynorvaline and related compounds

(All values are expressed relative to leucine, 1·00)

Solvent	γ-Hydroxy-norvaline	γ-Hydroxynor-valine lactone	δ-Hydroxy-norvaline	γ-Hydroxy-valine
Butanol-acetic acid*	0·50	0·76	0·38	0·46
t-Amyl alcohol-acetic acid†	0·39	0·49	0·31	0·36

* Butan-1-ol–acetic acid–water mixture (90 : 10 : 29, by volume).
† Upper phase of 2-methylbutan-2-ol–acetic acid–water mixture) 10 : 1 : 10, by volume).

The isolated material gave the following elementary analysis (in per cent): C, 45·2; H, 8·32; N, 10·2 ($C_5H_{11}NO_3$ requires C, 45·1; H, 8·33; N, 10·5). When treated with N-hydrochloric acid at 120° C for 1 h, it was converted largely into its lactone, which appeared initially as a yellow spot moving ahead of the amino-acid on paper chromatograms. The R_F values determined for γ-hydroxynorvaline and its lactone are given in Table 1 together with those for δ-hydroxynorvaline (II) and γ-hydroxyvaline (III), two isomeric amino-acids isolated from soybean seeds[3] and *Kalanchoe diagremontiana*, respectively. In all solvents tested, the isolated γ-hydroxynorvaline behaved exactly as authentic synthetic material[5], kindly provided by Dr. A. J. MacLeod.

The identity of the isolate was confirmed further by electrophoretic comparison with synthetic γ-hydroxynorvaline. When paper electrophoresis was performed, essentially as described by Gross[6], at *p*H 2·0 (formic–acetic acid buffer) for 1·5 h (60 V/cm, 40 m.amp), the synthetic compound was separated into its two diastereoisomeric forms, which moved 26·2 and 28·7 cm, respectively, towards the cathode. Somewhat surprisingly, the natural hydroxynorvaline also gave two spots, moving identically with those obtained from the synthetic compound, but present in different relative proportions. It is unlikely that γ-hydroxynorvaline was present in the original seeds as a mixture of isomers, and so a small amount of the amino-acid was isolated directly from two-dimensional paper chromatograms. In this instance only the fast-moving diastereoisomer was observed. Presumably, during the large-scale isolation, partial epimerization had occurred at the γ-carbon atom as lactone was formed on the ion-exchange resin. Under identical electrophoretic conditions, threonine moved faster than *allo*threonine and, by analogy, natural γ-hydroxynorvaline probably possesses a *threo* configuration.

Additional confirmation of the γ-hydroxynorvaline structure was obtained by treating the hydroxyamino acid (50 mg) with 55 per cent (w/v) hydriodic acid and red phosphorus at 130° C for 12 h when norvaline was produced (compare Fischer and Leuchs[7]). This was isolated using

a small 'Zeo-Karb 225' column and analysed as follows (in per cent): C, 51·1; H, 9·58; N, 11·8 ($C_5H_{11}NO_2$ requires C, 51·3; H, 9·48; N, 12·0).

Unfortunately this hydriodic acid treatment also effected complete racemization and so no information was obtained concerning the configuration at the α-carbon atom in natural γ-hydroxynorvaline. Optical rotation measurements on isolated γ-hydroxynorvaline (mixed diastereoisomers) gave $[\alpha]_D^{20}$ values of +22° ($c = 5$ in water) and +32° ($c = 2·5$ in glacial acetic acid). When measurements were made using a 2·5 per cent solution in 5 N hydrochloric acid, the freshly prepared solution exhibited a dextro-rotation. As lactone was formed, $[\alpha]_D^{20}$ decreased: finally, after standing overnight, the $[\alpha]_D^{20}$ became constant at −16°. The higher positive value determined for $[\alpha]_D^{20}$ in glacial acetic acid compared with that in water tentatively indicates an L-configuration at the α-carbon atom but, in view of several recorded exceptions to the Clough–Lutz–Jirgensons rule[8], this conclusion will require confirmation.

Paper chromatography has shown that γ-hydroxynorvaline is present in several other legume seeds including species of *Astragalus*. At present nothing is known concerning the metabolic relationships of this hydroxyamino acid in legume seedlings, but it could arise by γ-decarboxylation of γ-hydroxy-γ-methylglutamic acid (IV) which is present in another legume (peanut seedlings[9]) and other plant species[10].

The sweet pea seed was provided by Unwin's Ltd., Histon, Cambridge. I thank Mrs. Jean Retallick and Mr. A. Smith for their assistance in this work.

Effect of Oestradiol in Adrenal Corticoidogenesis: an Additional Step in Steroid Biosynthesis

Oophorectomy in the albino rat results in diminished pituitary adrenocorticotrophic hormone (ACTH) secretion and in diminished adrenal secretion of corticosterone[1]. The latter is demonstrable in peripheral plasma after injection of ACTH or following stress, in adrenal venous effluent, and in adrenal slices incubated *in vitro*. Administration of oestradiol-17β reverses these effects. Although the adrenal response to oestradiol may, in part, be mediated by changes in ACTH secretion, a direct effect is also suggested by the finding that oestradiol stimulates corticosteroid production when added to adrenal slices *in vitro*[2], and when administered to hypophysectomized, oophorectomized rats *in vivo*[3]. Additional investigations suggest an apparent inhibition of steroidogenesis in adrenal tissue after oophorectomy[4]. This communication reports observations giving a more specific definition of the relation of the ovary to adrenal function.

Female rats of the Sherman strain were oophorectomized when 30 days old and were not subjected to further manipulation for the next 6 weeks. Oestradiol-17β ('Estradurin', Ayerst) was then injected subcutaneously as a single depot dose of 100 μg/100 g body-weight. Investigations were carried out 2 weeks later. Adrenal homogenates were prepared and incubated for 60 min at 37° C under 95 per cent oxygen–5 per cent carbon dioxide. The reaction mixture contained: 0·154 M potassium chloride, 0·02 M sodium bicarbonate, $1·25 \times 10^{-3}$ M Ca^{++}, $3·3 \times 10^{-3}$ M glucose-6-phosphate, 10^{-3} M TPN, and 20 mg adrenal tissue/ml. 10 μg corticosterone was added to half the beakers before incubation. The incubates were extracted with chloroform and steroid production was measured in equal volumes by acid fluorescence[5], by ultra-violet absorption at 240 mμ, and by the blue tetrazolium (BT) reaction[6]. Fluorometry is the most specific of these methods for corticosterone, since other steroids which fluoresce are not produced in significant quantities by the rat adrenal cortex[7]. Ultra-violet absorption is based on the Δ-4,3-keto configuration in ring *A* which includes many other steroids, such as deoxycorticosterone, 18-OH-corticosterone and aldosterone, as well as corticosterone. The BT reaction is even less selective and requires only the C-20, 21 α-ketolic side chain.

The results of a typical experiment are summarized in Table 1. Corticosterone yields were significantly lower ($P < 0·01$) in adrenal homogenates from oophorectomized rats than those from intact or oestradiol-replaced animals when measured by fluorescence. Similar values were obtained with ultra-violet absorption. However, no difference between intact and oophorectomized rats was demonstrated with the BT reaction. Following addition of corticosterone at the outset of incubation, a 50 per cent loss of the added steroid occurred with the adrenal homogenates from oophorectomized rats when measured either by fluorescence or by ultra-violet absorption. No loss could be detected with the BT reaction.

Table 1. Steroid Production by Rat Adrenal Homogenates *in vitro**

Method	Direct incubation (μg/100 mg adrenal) Intact	Oophor.	Oophor. + oestradiol	Corticosterone added (μg/beaker remaining) Intact	Oophor.	Oophor. + oestradiol
Fluor.	35·0	20·3	41·0	9·5	5·4	9·2
Ultra-violet	44·6	20·2	53·4	10·2	5·4	11·0
BT	60·0	57·2	64·4	13·5	12·5	14·0

* Each value represents the mean of three observations.

These data indicate that total corticosteroid production by adrenal homogenates *in vitro* is not diminished by oophorectomy. However, the amount of corticosterone obtained is decreased, and this finding is consistent with previous observations[1]. The diminution in the yield of corticosterone may be explained by the capacity of adrenal tissue from oophorectomized rats to metabolize corticosterone further. The resulting metabolite(s) is characterized by a loss of the Δ-4,3-keto configuration in ring *A* but an unaltered side chain. I suggest that one effect of oestradiol is to inhibit the rate of the reaction responsible for the formation of this metabolite.

Additional data relating to this hypothesis were obtained by the addition of both cholesterol-26-^{14}C and cholesterol-4-^{14}C to adrenal homogenates prepared as described. Following incubation, isocaproic acid-^{14}C production was measured by the method of Ichii *et al.*[8], and corticosterone-4-^{14}C production by the addition of corticosterone-1,2-^{3}H with chromatography to constant ^{14}C : ^{3}H ratio on a column and four thin-layer systems with silica-gel *G*. Radio-isotopes were obtained from New England Nuclear Corporation. The chromatographic systems were: *cyclo*hexane–ethyl acetate, 2 : 8; ether; chloroform–acetone, 7 : 3; butyl acetate–methanol, 99 : 1. Measurements were made with a Packard Tri-Carb liquid scintillation spectrometer. The results are summarized in Table 2. Oophorectomy carried out in advance

Table 2. Products resulting from Incubation of Cholesterol-4-^{14}C and -26-^{14}C (0·2 μc. of Each/100 mg) with Rat Adrenal Homogenates *in vitro* (d.p.m./100 mg Adrenal Tissue/120 min)*

Product	Intact	Oophor.	Oophor. + oestradiol
Isocaproic acid-^{14}C	154,741	169,741	168,731
Corticosterone-^{14}C	48,639	30,432	48,206

*Each value represents the mean of three observations.

resulted in a significant reduction ($P < 0.01$) in the yield of corticosterone from labelled precursor, although the total amount of cholesterol converted to corticosteroids was not changed, as measured by the production of isocaproic acid-^{14}C. The observations based on unlabelled and labelled steroids are in accord.

The significance of a step (or steps) in the adrenal cortex for the metabolism of corticosteroid beyond corticosterone regulated by oestrogen is not clear. One possibility is that this mechanism provides a means of regulating the output of physiologically active steroid independent of that controlled by pituitary ACTH secretion.

These results will be discussed in greater detail in a subsequent publication. This investigation was supported in part by research grant (*AM*-03370) and research career development award (*AM*-K3-13960) from the U.S. Public Health Service. I thank Miss Lydia K. Brown and Miss Nancy L. Hough for their technical assistance.

Effect of Deuterium Oxide on the Relaxation of Glycerol-extracted Muscle

DEUTERIUM oxide is known to retard the contraction of living muscle[1–3]. The site of its action, however, remains obscure; it affects significantly neither the membrane excitation[4–6] nor the contraction of the proteins in glycerol-extracted muscle[5]. Deuterium oxide has, however, a differential effect on the contractile response to a number of nucleotides; whereas the interactions with adenosine triphosphate (ATP) and cytodine triphosphate (CTP) are not affected, those with inosine triphosphate (ITP) and uridine triposphate (UTP) are retarded[5]. The ATPase of myofibrils[6] and myosin *B*[7] is reduced by deuterium oxide under certain conditions; at neutral *p*H the myosin *B* ATPase is, however, not significantly affected[7]. In the case of ITPase, the reaction is always slower on substitution of deuterium oxide for normal water (H_2O) (ref. 7).

This communication reports additional observations on glycerol-extracted muscle. Preparations which have the property of spontaneous relaxation after ATP-induced contraction are known to lose this property on pre-soaking in water–salt solution for variable periods of time[8,9]. It will be shown that in deuterium oxide the rate of this loss is reduced.

Rabbit psoas muscles were used which had been extracted in 50 per cent glycerol[10] for 3–16 weeks. Fibre bundles about 6 cm long and about 0·2 mm thick were dissected at room temperature and cut in half; one-half was observed in deuterium oxide and the other in normal water.

The bundles were pre-soaked in either deuterium oxide (99·8 per cent) or distilled water for periods of time varying from 15 min to 9 h and then mounted for 2 min in an experimental bath containing deuterium oxide– or water–salt solutions, respectively. The solutions contained 0·16 M potassium chloride, 0·01 magnesium chloride and *tris*-maleate buffer 0·02 M, *p*D 6·8, *p*H 7·2 (ref. 11); in some instances buffer was not used. ATP (final concentration 4 mM) was applied and, later, calcium chloride (final concentration 1 mM). The solutions were stirred continuously. The isometric tension was measured with a force-displacement transducer and direct-writing oscillograph (Grass).

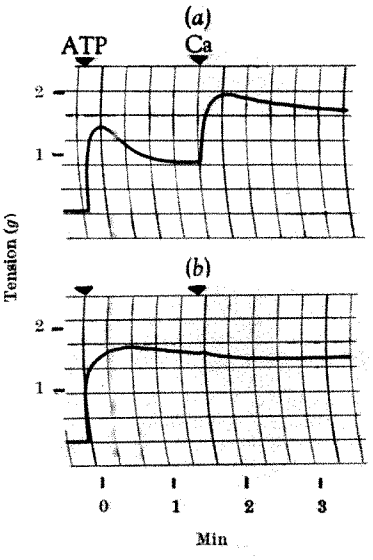

Fig. 1. (*a*) Isometric tension recording of psoas bundle extracted in 50 per cent glycerol at −20° C for 3 months. The bundle was soaked in deuterium oxide for 0·5 h and then placed in a deuterium oxide-salt solution. At 'ATP', 4 mM (final concentration) of ATP was added. This caused partial contraction followed by relaxation. At 'Ca', 1 mM (final concentration) of calcium chloride was added, resulting in recontraction. (*b*) Recording of the paired bundle which was soaked in normal water for 0·5 h and then placed in water-salt solution. ATP caused a full sustained contraction uninfluenced by calcium chloride

Muscle bundles, pre-soaked in water for 0·5–1 h, usually contracted maximally in response to ATP, did not relax spontaneously and were not influenced by subsequent addition of calcium chloride. In comparable experiments in deuterium oxide, on the other hand, there was usually spontaneous relaxation with recontraction occurring on addition of calcium chloride (Fig. 1). Table 1 summarizes the results and demonstrates that in general deuterium oxide, as compared with water, retarded the rate of loss of the relaxing property of the muscle. Deoxycholate, known to inactivate the relaxing factor[12,13], prevented the relaxation in deuterium oxide.

Table 1. SUMMARY OF RESULTS, COMPARING THE INFLUENCE OF DEUTERIUM OXIDE WITH THAT OF NORMAL WATER ON THE LOSS OF SPONTANEOUS RELAXATION IN GLYCEROL-EXTRACTED MUSCLE

No. of experiments	Period of soaking in water or deuterium oxide	Results	
		Deuterium oxide	Water
20	30 min—9 h	Spontaneous relaxation	No spontaneous relaxation
12	15 min—1 h	Relaxation velocity 2–3 times that in water	
10	15 min—1 h	Relaxation velocity equal to that in water	
5	30 min—1 h	No spontaneous relaxation	No spontaneous relaxation

The loss of spontaneous relaxation consequent on pre-soaking the preparation in water is due, presumably, either to the inactivation of the relaxing factor (sarcoplasmic reticulum) or to some soluble fraction diffusing out of the muscle. It has been suggested that water inactivates the relaxing factor and that this may be reversed by glycerol and sucrose[14].

It appears that deuterium oxide decreases the rate of the inactivation of the relaxing factor. Deuterium oxide will not, however, reverse the inactivation caused by water.

While deuterium oxide is known, of course, to retard reaction rates[15,16], there is no obvious suggestion as to the particular reactions affected in the present investigation.

Effect of Kidney Beans (*Phaseolus vulgaris*) on Plasma Tocopherol-level and its Relation to Nutritional Muscular Dystrophy in the Chick

Dietary use of raw kidney beans (*Phaseolus vulgaris*) is known to increase the incidence of liver necrosis in weanling rats[1] and nutritional muscular dystrophy in chicks[2]. Although this effect has been attributed to some heat labile antagonist(s) to vitamin E, the nature of such antagonists and the mechanism of their action are unknown.

The purpose of this note is to report some findings which explain why raw kidney beans decrease the biological activity of vitamin E and what is the interrelationship of such process in the development of muscular dystrophy in chicks.

One-day-old White Plymouth Rock × Vantress chicks from vitamin E-depleted hens were used in this investigation. Each treatment consisted of replicated lots of ten male chicks housed in electrically heated battery brooders with wire-mesh floors. Feed and water were supplied *ad libitum*. The basal diet used was low-vitamin E casein-isolated soybean protein-torula yeast diet as described by Scott and Calvert[3], with modifications as follows: the diphenyl-*p*-phenylenediamine was omitted and the diet was supplemented with 1 per cent L-arginine, 0·0125 per cent ethoxyquin to prevent encephalomalacia and 0·1 p.p.m. selenium (as sodium selenite) to prevent exudative diathesis.

Chicks were killed at the end of the 4-week experimental period and scored for muscular dystrophy. The scoring scale ranged from zero, for absence of dystrophy, to 4, for maximal dystrophy. The average scores were determined by dividing the total scores for each group by the number of chicks in that group. Blood samples were taken from the chicks by heart puncture just before killing them. The heparinized blood was centrifuged at 2,500 r.p.m. for 10 min and the plasma was carefully pipetted off and frozen immediately for subsequent tocopherol analysis. Total plasma tocopherols were determined by the method of Quaife and Harris[4].

Results in Table 1 show the effect of raw and autoclaved kidney beans on plasma tocopherol-level and its relation to muscular dystrophy in chicks. Chicks on basal vitamin E low diet showed maximum symptoms of muscular dystrophy and a significantly low level of plasma tocopherol. Addition of 10 mg *d*-α-tocophenyl acetate to the basal diet increased the plasma tocopherol-level five-fold and reduced the muscular dystrophy to a minimum. Such direct correlation between the plasma tocopherol-level and the incidence of muscular dystrophy was reported earlier by Scott and Desai[5]. When 50 per cent raw kidney beans were included in the basal diet containing 10 mg *d*-α-tocophenyl acetate, the plasma tocopherol-level was significantly reduced and the muscular dystrophy was elevated to give a score of 3·6. On the other hand, when 50 per cent of raw kidney beans were substituted with an equivalent amount of autoclaved kidney beans, the plasma tocopherol-level was quite improved and the muscular dystrophy was correspondingly reduced.

Table 1. Effect of Raw and Autoclaved Kidney Beans on Plasma Tocopherol-level and Muscular Dystrophy in Chicks

Dietary treatment	Muscular dystrophy score (0–4)	Plasma tocopherol-level (μg/100 ml.)
Basal low vitamin E diet	4·0	159
Basal diet + 10 mg *d*-α-tocophenyl acetate/kg diet	0·8	887
Basal diet + 50 per cent raw kidney beans + 10 mg *d*-α-tocophenyl acetate/kg diet	3·6	227
Basal diet + 50 per cent autoclaved * kidney beans 10 mg *d*-α-tocophenyl acetate/kg diet	0·2	500

* Autoclaved at 15 lb. pressure for 30 min.

It appears from these results that at least one and the most important reason for this muscular dystrophy inducing effect of raw kidney beans is the interference in absorption and/or retention of vitamin E in the body. The interfering factor(s) could be specific heat-labile proteins or lipoproteins which bind vitamin E and make it unavailable to the body. The significance of effective absorption and retention of tocopherols for specific functions, such as prevention of muscular dystrophy, has already been discussed[6,7].

I thank Dr. M. L. Scott and Dr. D. E. Hogue, Cornell University, for providing the research facility and the kidney bean preparations.

PHYSIOLOGY

Cerebellar Activity, Apneustic Breathing, and the Neural Control of Respiration

Apneustic breathing, characterized by deep, sustained inspiratory activity, has figured prominently in theories on the neural control of respiratory rhythmicity[1]. This intriguing respiratory phenomenon has been described in the vagotomized, midpontile decerebrate animal[2–4]. In this preparation, the Hering–Breuer afferent system in the vagi and the pneumotaxic area in the rostral pons have been eliminated. Both the Hering–Breuer and the pneumotaxic influences appear to be predominantly inhibitory to the inspiratory mechanisms of the lower brain stem[4]. However, the apneustic area in the lower pons is not destroyed by midpontile decerebration and continues to provide a powerful facilitatory influence on the inspiratory neurones of the medulla[2–4]. In the presence of apneustic facilitation and the absence of Hering–Breuer and pneumotaxic inhibition, the medullary inspiratory neurones are excessively stimulated. The resultant excessive activity of the inspiratory neurones produces apneustic breathing[1–4].

In the vagotomized, midpontile decerebrate animal, the cerebellum as well as the caudal pons and the medulla remain intact. Thus the cerebellum may play a significant part in the phenomenon of apneustic breathing and, if such is the case, in the neural control of respiratory rhythmicity. The data obtained in the present work indicate that apneustic breathing and respiratory rhythmicity are indeed significantly affected by the cerebellum.

Thirty-five adult cats were used in this investigation. Anaesthesia was induced and maintained with ether until, in twenty-six experiments, the animals were decerebrated. Decerebration was effected at the midpontile level by a combination of arterial occlusion and brain stem transection procedures[5,6]. This decerebration technique normally minimized the problem of haemorrhage.

Cerebellar depression was effected by ischaemic, pharmacological, and surgical procedures. One or combinations of these procedures were utilized in each experiment. Ischaemic depression of cerebellar function was achieved by occlusion of the anterior and posterior cerebellar arteries with silver clips. Pharmacological depression was effected by application of procaine (1 per cent) or xylocaine (1 per cent) to the surface of the cerebellum or by injection of 0·05 ml. of these drugs subcortically. Surgical depression procedures consisted of ablation of part or all of the cerebellum by suction. The efficacy of the ischaemic technique was evaluated by post-mortem study of the brains after injection of vinyl acetate into the common carotid and vertebral arteries. The pharmacological application and injection areas were tagged with dyes. Ablation sites were determined by post-mortem examination of the brains after fixation.

Fifteen vagotomized, midpontile decerebrate cats exhibiting apneustic breathing and decerebrate rigidity were subjected to suppression of cerebellar function. In thirteen of these animals, significant enhancement of inspiratory activity was produced. This enhancement was expressed as an increase in the depth of inspiration, as an increase in the duration of inspiration, or as an increase in both inspiratory depth and duration. Respiratory rate, when altered, was decreased. Pulmonary ventilation per unit of time was increased, decreased, or unchanged depending on the relative alterations in respiratory depth and rate. Heart rate and arterial blood pressure tended to remain at normal or supranormal levels in these vagotomized, midpontile animals[7,8]. Decerebrate rigidity was often visibly augmented by cerebellar depression.

Eleven cats were subjected to midpontile decerebration and cerebellar depression prior to vagotomy. Midpontile decerebration typically produced a moderate increase in the depth of inspiration and, in some animals, a decrease in the rate of respiration. The long sustained inspiratory activity characteristic of apneustic breathing did not appear. Later, ischaemic, pharmacological, or surgical depression of cerebellar function in these midpontile animals markedly enhanced either or both the depth and the duration of inspiratory activity. In eight animals in this series, apneustic breathing patterns developed in spite of the integrity of the vagi (Fig. 1). Subsequent vagotomy produced further augmentation of inspiratory depth and duration.

Nine cats under ether anaesthesia were subjected to cerebellar depression without prior decerebration or vagotomy. Suppression of cerebellar activity in these animals typically produced significant augmentation of inspiratory depth. Respiratory rate, when altered, was almost invariably decreased. One animal exhibited a prolongation of inspiration that was suggestive of apneustic breathing. Moderate spasticity appeared in some of these animals; heart rate and arterial blood pressure tended to remain within normal ranges.

Analysis of the effects of depression of selective portions of the cerebellum revealed that augmentation of inspiratory activity was obtained from suppression of either the anterior or the posterior lobe of the corpus cerebelli. However, inspiratory enhancement was obtained more readily and was of greater magnitude when the anterior lobe was suppressed. Depression of function of both the anterior and the posterior lobes often produced greater augmentation of inspiratory activity than depression of either lobe alone.

Other investigators have revealed cerebellar effects on respiration. Stella[9] reported that ablation of the cerebellum in intercollicular dogs enhanced pulmonary ventilation. Moruzzi[10] found that faradic stimulation of the anterior lobe in precollicular cats suppressed respiratory activity, particularly the reflex respiratory responses elicited by occlusion of the common carotid arteries or by intracarotid injection of potassium cyanide. Zanchetti and Zoccolini[11] found that cerebellar stimulation in thalamic cats produced sham-rage outbursts which included marked hyperpnoea. More recently, Stella and Stevan[12] reported that cerebellar stimulation in intercollicular dogs may produce either facilitation or inhibition of respiratory activity.

In contrast with the investigations cited above in which cerebellar effects on respiration were studied in high decerebrate animals with the pontile pneumotaxic centre and the vagal Hering–Breuer system intact, the investigation described here explored cerebellar influences both in the presence and in the absence of pneumotaxic and Hering–Breuer activity. Consequently, the data from the present study can be related more directly to the basic neural mechanisms responsible for the phenomenon of apneustic breathing and for the neural control of respiratory rhythmicity. These data clearly indicate that the cerebellum in the cat provides a tonic, predominantly inhibitory influence on the inspiratory mechanisms of the lower brain stem. This cerebellar inhibition could be exerted on the excito-inspiratory neurones of the pontile apneustic centre, the inspiratory neurones of the medullary respiratory centre, or on both of these inspiratory mechanisms. The nature of the cerebellar influence places it in a position parallel to the inhibitory influences of the pneumotaxic centre and the Hering–Breuer system and antagonistic to the powerful facilitatory influence of the apneustic centre. Both the anterior and the posterior lobes of the corpus cerebelli, but particularly the anterior lobe, appear to give rise to this cerebellar respiratory activity.

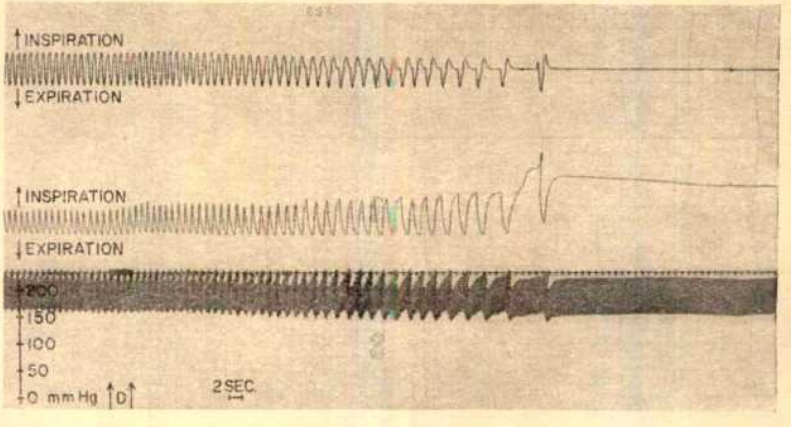

Fig. 1. Polygraph record of respiratory response to ischaemic depression (*D*) of cerebellar activity in a midpontile decerebrate cat, vagi intact. Sequence of tracings from the top: 1, respiration recorded with a Grass *PT* 5 transducer; 2, respiration recorded with a pneumograph; 3, arterial blood pressure recorded with a Statham *P* 23 transducer. Note the sustained inspiratory activity which developed approximately 1 min after *D*

Heat Stress Degranulation of the Basophil Leucocyte in Man

Long an obscure but distinctive type of leucocyte, the basophil has in recent years been shown to play an active part in the immediate-type hypersensitivity reaction[1,2]. Evidence is accumulating that this cell releases its granules containing histamine and heparin in the presence of an antigen and a reactive antibody. These morphological changes of degranulation, however, are not specific nor limited to the allergic state. Certain drugs may induce similar degranulation in the complete absence of any sensitivity[3]. The investigation reported here extends our view of the role of this cell, since it shows that, in man, acute heat stress also induces the morphological changes of degranulation in the circulating basophil.

Ten normal, healthy, White and Negro male adults served as subjects. All medication was interdicted for 2 weeks before and during the entire investigation. Heat stress was achieved by exposing the men to an environment of 120° F with 50 per cent relative humidity for 30-min periods. To assess possible acclimatization, the 30-min stress was repeated daily for 7 days. Heparinized venous blood samples were obtained for absolute and morphological basophil counts[2] immediately before, immediately after, as well as 1 and 4 h after each daily heat stress. Control counts and morphological assessments were undertaken before and 1 week after the last heat stress. Cells were classified as normal or degranulated, that is, having fewer than normal granules, showing cytological evidence of extrusion of granules, or showing less staining. Table 1 summarizes representative data showing that, although the basophil count remained essentially normal, the subjects experienced a significant change in the morphology of the cell immediately after 30 min of heat stress. This was evident at 2 h, as well as at 4 h, and to a lesser degree at 24 h.

In nine of the ten subjects, 30 min of high temperature produced a dramatic increase in the number of basophils showing degranulation. The effect persisted for the entire 7 days, acclimatization not being evident. However, after a week of no exposure in the thermal chamber, the number of degranulated basophils returned to, or below, normal in each of the men.

The mechanism and significance of this heat-induced change in the basophil remain unknown, but it is interesting to speculate that perhaps the basophil releases the vasodilator histamine in response to elevated temperatures. This could thus serve as an adaptive mechanism since body temperatures did not rise appreciably during the 30 min of stress. It should be noted that the basophil is thermo-sensitive *in vitro*, remaining normal in chilled blood for longer than in blood kept at 37° C. Further investigation of the factors accounting for this stress-induced degranulation of the basophil would seem to be indicated.

This investigation was supported by Public Health Service research grant *HE* 07428-03 from the Division of Research Grants, National Institutes of Health.

Cholinesterase in the Mammalian Kidney

Cholinesterase activity has been demonstrated in portions of the renal tubule[1,2], but no one has determined which segment of the nephron contains the enzyme. This is surprising as cholinesterase activity is known to be associated with sodium transport in a number of tissues and might therefore be associated with sodium transport in the kidney. Koch[3] showed that cholinesterase is important for sodium transport through the gill epithelium of the freshwater crab and for sodium absorption from the anal papillae of the insect larva *Chironomus plumosus*. The gills of fish transport sodium and contain cholinesterase[4]. In frog skin Koblick *et al.*[5] found an excellent correlation of cholinesterase activity with average short circuit current and thus with sodium transport. Kamento[6] found cholin-

esterase in the gills and kidney of the crayfish, and his data suggest that at both sites it is involved in sodium regulation.

To demonstrate cholinesterase activity, I have used the method of Coupland and Holmes[7] on 20μ frozen sections of kidney, fixed overnight in 10 per cent formol saline. The optimal conditions for clearly defined staining of renal tubules are incubation for 5 h in a medium with acetylcholine as the substrate and an acetate buffer system to bring the final *p*H of the medium to five.

In the kidneys of twelve rats, four rabbits, four cats and two mice that had drunk freely before death, the only tubular cholinesterase activity was in short segments at the junction of the inner and outer strip of the outer medulla, beside the upper part of the vasa recta bundles. The exact segment could not be identified.

Six rats were given no water for 24 h before they were killed, so that they were producing a concentrated urine. The staining of their renal tubules was both more intense and more widespread than in the hydrated animals, extending from the inner part of the cortex to the junction of the outer and inner medulla (Fig. 1). These segments were identified as the thick ascending limbs of loops of Henle. The most intense staining was in tubules alongside the vasa recta and efferent arterioles which supplied them. By microdissection of portions of kidney in which the vessels had been injected[8], it was found that these tubules originate in juxtamedullary glomeruli and have long loops of Henle (Fig. 2).

The addition of 62*C*47 *h* di-iodide (10^{-5} M) to the incubating medium did not affect the cholinesterase activity of the tubules. It was completely inhibited by eserine (10^{-5} M) and 'Mipafox' (10^{-5} M). This is evidence that the enzyme present in the tubules is a pseudocholinesterase.

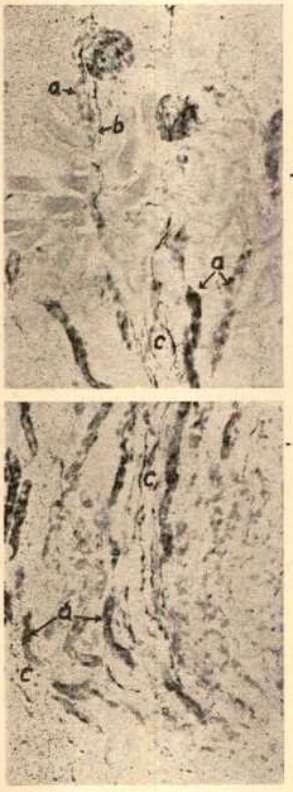

Fig. 1

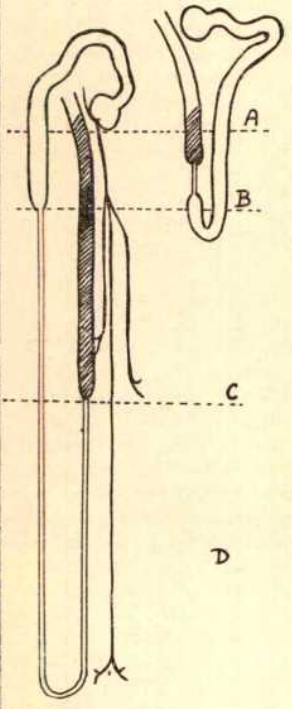

Fig. 2

Fig. 1. Sections from the medulla of a dehydrated rat showing (*a*) cholinesterase activity in the tubules, (*b*) efferent arteriole, and (*c*) bundle of vasa recta. (× 60)

Fig. 2. Diagram of the segments of tubule with cholinesterase activity. Black shading, hydrated rats. Cross-hatching, dehydrated rats. *A*, Cortex; *B*, outer strip; *C*, inner strip; *D*, inner medulla

It has been suggested that the counter-current mechanism for concentration of urine in the renal medulla depends on the active transport of sodium out of the ascending limb of the loop of Henle, and it is in the thick portion of this limb that I have found cholinesterase activity. It is increased in dehydrated animals producing a concentrated urine. It is therefore tempting to suggest that cholinesterase activity is linked with sodium transport in the mammalian nephron, and the work is being continued to see what further evidence there is for this.

Stability of Adaptation of Critical Flicker Fusion Frequency to Intermittent Light

THE modification of critical flicker fusion frequency by intermittent light of varying frequency is unchanged by such physiological procedures as hyperventilation and rebreathing[1], and by drugs[2,3], which are known to alter mean critical flicker fusion frequency. Wave-length and the light–dark ratio of the light source[4] are important factors in determining binocular critical flicker fusion frequency, and the state of luminance of the opposite eye in determining monocular critical flicker fusion frequency[5]. Their possible influence on the adaptation phenomenon has, therefore, been investigated.

Light–dark ratio. Fifteen subjects were exposed on three days to light flickering at 20 and 50 c/s for 1 min after which ascending (*A*) or descending (*D*) thresholds of critical flicker fusion frequency were determined using Turner's method[6]. The order of measurement was randomized in a Latin square sequence. The light–dark ratio of the adapting light source varied on the 3 days between 9–1, 5–5, and 1–9, while that of the source used for determining critical flicker fusion frequency was maintained at 5–5.

The results were subjected to analysis of variance and are shown in Table 1. The difference (*d*) between mean values of critical flicker fusion frequency after adaptation to light at 20 and 50 c/s, with a light–dark ratio of 9–1, is not significantly different from that at light–dark ratios of 5–5 and 1–9. The mean thresholds after exposure to adapting frequencies with a light–dark ratio of 9–1 were significantly higher ($P < 0.01$) than with a light–dark ratio of 5–5 or 1–9. It may be that the first light produced a higher state of retinal light adaptation, which would be associated with higher critical flicker fusion frequency[4].

Wave-length. Eight subjects were exposed in random sequence to adapting lights at 20 or 50 c/s for 1 min, and *A* and *D* thresholds measured. The wave-length and luminance of the adapting light were either 565 mμ and 35 lumens/ft.² (yellow) or 620 mμ and 40 lumens/ft.² (red). The light source used to determine critical flicker fusion

Table 1. MEAN OF ASCENDING AND DESCENDING CRITICAL FLICKER FUSION FREQUENCY (C/S) AFTER EXPOSURE TO INTERMITTENT LIGHT AT 20 AND 50 C/S FOR 1 MIN WITH LIGHT–DARK RATIOS OF 9–1, 5–5, 1–9

		Frequency of adapting light (c/s) 20	50	*d*
Light–dark ratio of adapting light	9–1	31·30	32·10	0·80
	5–5	30·60	31·60	1·00
	1–9	30·75	31·60	0·85

$n = 30$ *S.E.* of difference = 0·102 c/s. 5 per cent critical difference = 0·204 c/s.

Table 2. Mean of Ascending and Descending Critical Flicker Fusion Frequency (c/s) after Exposure to Intermittent Light at 20 and 50 c/s for 1 min using a Red (*R*) or Yellow (*Y*) Light ($n = 16$)

	Frequency of adapting light (c/s) 20	50	d_1	Dd_1
R	31·66	32·50	0·84	0·10
Y	31·05	31·99	0·94	
d_2	0·61	0·51		
S.E. of difference		0·216		0·308

frequency was a neon lamp (wave-length 570–610 mμ, luminance 35 lumens/ft.²).

The results are shown in Table 2. The difference (d_1) between mean thresholds after adaptation to 20 and 50 c/s for 1 min with a red light was not significantly different from that with a yellow light. However, the mean thresholds after exposure to the red light were significantly greater ($P < 0·02$) than to a yellow light (d_2). Hecht and Schlaer[7] showed that colour of the light source was an important variable in determining critical flicker fusion frequency, although Landis[4] directed attention to the difficulty in controlling luminance and colour separately. This experiment demonstrates, however, the effect of previous adaptation to light of different wave-lengths on the subsequent determination of critical flicker fusion frequency. It is unlikely that the small difference in luminance between the adapting light sources contributed significantly to this effect.

Luminance of the opposite eye. Lipkin[5] showed that the critical flicker fusion frequency of one eye was related to the state of luminance of the contralateral eye. This was confirmed by a simple experiment in which ascending thresholds were measured in the left eyes of fourteen subjects after exposure for 1 min to light at 50 c/s with the right eye either adapted to the same background illumination as the left (1 lumen/ft.²) or dark adapted by being completely covered for 5 min. The mean critical flicker fusion frequency in the light-adapted state was 32·09 c/s and in the dark-adapted state 33·11 c/s (*S.E.* of difference = 0·30 c/s $P < 0·01$).

The experiment was now repeated in eight subjects with measurements of *A* and *D* thresholds in the left eye after exposure to 20 and 50 c/s adapting light, while the right eye was either light- or dark-adapted.

The results are shown in Table 3. They confirm a significant difference ($P < 0·01$) between the mean thresholds under conditions of light and dark adaptation (d_2), but the difference between mean thresholds after 20 and 50 c/s (d_1) with light adaptation was not significantly different from that with dark adaptation.

Table 3. Mean of Ascending and Descending Critical Flicker Fusion Frequency (c/s) of Left Eye after Exposure to Intermittent Light at 20 and 50 c/s for 1 min with the Right Eye Light (*L*)- or Dark (*D*)-adapted ($n = 16$)

		Frequency of adapting light (c/s) 20	50	d_1	Dd_1
State of adaptation	*L*	29·53	30·64	1·11	0·08
	D	30·46	31·49	1·03	
	d_2	0·93	0·85		
S.E. of difference			0·312		0·442

It appears, therefore, that the adapting effect of intermittent light of varying frequency on critical flicker fusion frequency is unaltered by changing the light–dark ratio or wave-length of the adapting light, or the state of light adaptation of the opposite eye. It has been suggested[1,6] that this phenomenon may have its counterpart in similar neurophysiological mechanisms of adaptation in other modalities where judgments have to be made and frames of reference established[8]. It is, perhaps, appropriate that such a phenomenon, so basic in the economy of the organism, should be stable and unaltered by physiological and pharmacological procedures which readily modify the actual threshold. Further investigation is indicated to determine the stability of intersensory adaptation[9].

We thank the staff of the electronics department of this hospital for help in construction of the apparatus, and the board of governors for financial assistance to D. S. P. One of us (P. T.) is in receipt of a Wellcome senior research fellowship in clinical science.

PHARMACOLOGY

Water and Electrolyte Changes in Cardiac and Skeletal Muscle of Cats Late in Haemorrhagic Shock

Coleman and Glaviano[1] found, in hearts removed from dogs late in post-oligaemic irreversible shock, an increase in potassium, a decrease in sodium, an increase in water which was not significant statistically, and no change in chlorine content per kg of fat-free dry tissue. These changes in cardiac water and electrolyte content were different from those found in congestive heart failure in the dog by Benson *et al.*[2] and Yankopoulos[3] (increased sodium, chlorine, and water). Coleman and Glaviano concluded that "the results of these investigations imply that the gradual decline of blood pressure in haemorrhagic shock does not stem from myocardial failure". I feel that this conclusion is more general than can be justified, either by their data, or by my data or those of others which will be discussed here.

My data confirm and extend those of Coleman and Glaviano in another species, the cat. My investigations were performed in 1959 by the following method: The tissues were blotted, dried to constant weight, defatted with ethyl ether, and then powdered in a mortar prior to electrolyte determination. Sodium and potassium were measured by flame photometry after an aliquot of powder was ashed by heat, while chlorine was titrated potentiometrically in an aqueous solution of dried powder. My control values were similar to those reported by Robertson and Peyser[4] for the cat.

In hearts removed from cats late in post-oligaemic irreversible shock I have found a significant ($P < 0·05$) increase in potassium and in water content, a decrease in sodium which was not statistically significant, and no change in chlorine content (see Table 1). These results are essentially in agreement with those of Coleman and Glaviano and indicate that the heart of the shocked cat reacts in these respects as does the heart of the dog.

Included in my investigation were the diaphragm, which like the heart continued to contract during ischaemia,

Table 1. Water and Electrolyte Content of Various Muscles and of Plasma in the Shocked Cat

	Water (g)		Potassium (m.equiv.)		Sodium (m.equiv.)		Chlorine (m.equiv.)	
	C	*S*	*C*	*S*	*C*	*S*	*C*	*S*
Heart	3,715	4,103*	355	468*	186	173	148	161
Diaphragm	3,203	3,395	390	457*	124	103*	92	78*
Gracilis	3,242	3,433	423	441	95	102	69	66
Plasma	—	—	3·5	6·8*	151	151	121	119

* $P < 0·05$. Values are in grams or m.equiv. per kg fat-free dry tissue or per litre of plasma.
C, Control. *S*, Shock.

and the gracilis muscle, which did not. Water and electrolyte changes in the diaphragm were similar to those in the heart. There were no significant changes in the gracilis muscle. In the plasma, only potassium was significantly increased.

Changes in muscle water and electrolytes in shock, therefore, were not limited to the heart. Similar electrolyte changes were present in another muscle, the diaphragm, which continued to work during the development of shock. Likewise, in congestive heart failure in dogs, Benson *et al.*[2] found, in the psoas muscle, used as a control, electrolyte changes which were quite similar to those found in the heart. Finally, Robertson and Daniel[5] found no electrolyte changes in cat and dog hearts which had been made to fail by treatment with large doses of pentobarbital. It is worthy of note that although haemorrhagic hypotension is accompanied by prolonged elevation of blood-levels of catecholamines (Watts and Bragg[6]), the changes in cardiac water and electrolytes in shock are not the same as those following large doses of epinephrine in the cat (increased water, potassium, sodium, and chlorine), reported by Robertson and Peyser[4]. In view of these several observations, it seems unwarranted to draw any conclusions, either from the data of Coleman and Glaviano, or from my data, concerning the presence of myocardial failure in shock.

There is a considerable amount of evidence to support the statement of Robertson and Peyser[7] that "calculations of the absolute size of the extracellular volume of cardiac muscle from plasma and tissue electrolyte concentration appear liable to gross error". Nevertheless, because potassium content and calculated intracellular potassium concentration in cardiac muscle remained high, while odium content and calculated intracellular sodium concentration remained low, I believe that more specific conclusions can be drawn, which were also drawn by Coleman and Glaviano, that failure of the transport mechanism for potassium and sodium in the heart muscle, and therefore also a marked deficit in myocardial energy metabolism, are not primary factors in the pathogenesis of irreversible shock.

IMMUNOLOGY

Sex Difference for Immune Depression and Runting in Neonatally Thymectomized Mice

AN amazing difference with regard to wasting following thymectomy has been observed between male and female hamsters; males showed severe runting even if thymectomized at up to 4 weeks of age, while females never runted at all[1]. No such differences have been reported for other species, though there may be such a difference for neonatally thymectomized rats (R. A. Good, personal communication).

In the course of our investigations concerned with carcinogen-induced tumours in relation to immune depression[2], the degree of wasting and the homograft reactivity of male and female mice thymectomized at birth had to be determined. The data, presented in Table 1, indicate also that in mice a sex difference may exist as far as runting is concerned as well as with regard to immune depression, the latter correlating well with the severity of the wasting syndrome.

C57BL and $(CBA \times C57BL)F_1$ mice were thymectomized within 24 h after birth according to Miller's technique[3]. When 8–10 weeks of age, all mice except the severely ill ones received a skin homograft (*CBA* skin on *C57BL* mice, $(RF \times C57BL)F_1$ skin on $(CBA \times C57BL)F_1$ mice; skin donors were female). In sham-operated controls, skin grafts in these combinations were always rejected within 2 weeks.

Table 1

No. of thymectomized mice	Runting: Fatal within 6 ms.	Runting: Not fatal within 6 ms.	Runting: % Runting*	Homograft reactivity: No. of mice grafted	Graft rejection: <2 wks.	Graft rejection: 2–3 wks.	Graft rejection: >3 wks.	% with depressed homograft reactivity*
Males 44[a]	21	8	66	32	7	7	18[c]	78
Females 35[b]	9	3	34	28	15	8	5[d]	46

* Differences between the groups are statistically significant at the 1 per cent level.
a, 24 *C57BL*, 20 $(CBA \times C57BL)F_1$; *b*, 18 *C57BL*, 17 $(CBA \times C57BL)F_1$; *c*, 14 died runted with intact skin grafts; *d*, all died runted with intact skin grafts.

Table 1 depicts the incidence of runting and the degree of the depression of homograft reactivity in these mice. Only mice without a trace of histologically demonstrable thymic remnants in serial sections of the upper mediastinum are included in the table. There was no strain difference within the sexes for the two parameters so that data for each sex could be pooled.

Apparently there was a significantly higher incidence of wasting and a stronger depression of homograft reactivity in the males. Early wasting, starting during the second and third months, was fatal in both sexes and the skin grafts were invariably kept intact until death. The mice with non-fatal runting, starting mostly after the third month, usually kept their skin graft from 3 to 10 weeks, while grafts on apparently healthy thymectomized mice rarely survived longer than 3 weeks. A parallel can therefore be drawn between the severity of wasting and the degree of immune depression.

Incidentally, if our figures are compared with data reported previously by others, one is struck by the comparatively low incidence of fatal runting and the moderate degree of immune depression especially in our female mice. Invariably fatal runting and a very high degree of immune depression following neonatal thymectomy have been reported by some authors for several mouse strains, including the *C57BL* that was also used in our experiments. This difference might, of course, be attributed to the possession of a more mature lymphatic system at birth by the particular sub-line used. It might be thought that the incapacity to reject foreign skin grafts should not in part be attributed to the physical deterioration of those animals due to infections rather than the deficient 'priming' of the lymphatic system *per se*. When infection was ruled out as a factor, as in the experiments by McIntire *et al.*[4] on germ-free mice, very little runting was seen and homograft reactivity was only slightly impaired.

To explain the lower incidence of runting and the lower degree of immune depression in female mice as compared to males, one might again assume that females are, at the time of birth, immunologically more mature than males. In that case neonatal thymectomy would less frequently lead to a wasting syndrome, whether this be the consequence of an auto-immune reaction subsequently leading to lymphatic atrophy and infections[5] or of a primarily deficient development of the lymphatic system followed by infections[3]. The strikingly dissimilar consequences of thymectomy in female and male hamsters, however, would implicate the sex hormones as a cause for this difference[1]. Oestrogens have in fact been shown to cause an increased mitotic index in lymphoid tissues[6] and evidence that female mice can be more reactive im-

munologically than males[7] would indeed suggest an influence of sex hormones on immune reactivity. Such an influence might also be operative in mice after neonatal thymectomy.

Inter-breed, Intra-breed and Autoplastic Chimerae of the Domestic Fowl

In 1956 one of us[1] developed a technique of grafting the forebrain region on the chicken embryo, which then underwent more or less normal development as a chimera[2,3]. Only a few of the chimeric embryos hatched and lived (Table 1). In the work reported here, three random-bred breeds of chicken were used: Barred Rock, White Leghorn and Rhode Island Red. The majority of the chimeric birds which hatched developed from reciprocal graftings between the embryos of Rhode Island Red and White Leghorn breeds. 502 inter-breed, 19 intra-breed and 68 autoplastic operations were performed. Fourteen inter-breed, one intra-breed and five autoplastic birds hatched. As these figures show, the percentage of individuals able to hatch in the inter-breed chimeric embryos was very low, whereas in the autografted embryos, although the number of embryos operated on was small, this percentage was considerably higher. One of the reasons for this is the difficulty of matching the transection plane on the recipient with that of the donor of the graft. As the self-regulating capacity of the embryo at the operation stage is quite limited, the appearance of supernumerary parts is the result. Such embryos never hatch.

As shown in Table 1, ten between-breed compound birds survived for periods longer than 2 weeks. Of these, one White Leghorn–Rhode Island Red male and one Rhode Island Red–White Leghorn female lived more than 3 years, and another Rhode Island Red–White Leghorn female, still alive, is now more than 5 years old (Fig. 1). Most of these birds showed lowered viability, presumably caused by the operation. They also seemed highly susceptible to infectious diseases. The cause of death of some of them could not be diagnosed.

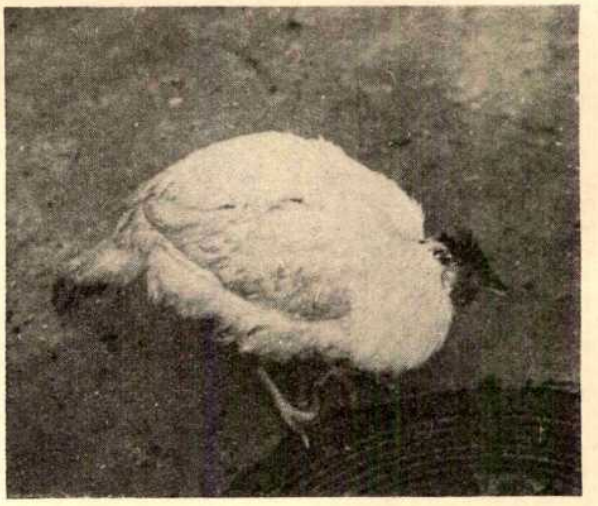

Fig. 1. Inter-breed compound ♀ No. 6. Body: White Leghorn; head: Rhode Island Red. Microphthalmia of left eye, crest underdeveloped. 5 years old

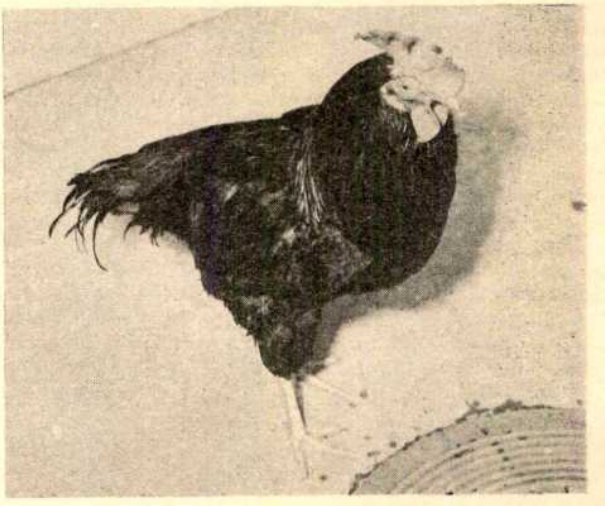

Fig. 2. Inter-breed compound ♂ No. 2. Body: Rhode Island Red; head: White Leghorn. Note: drooping crest; donor of graft a female. More than 3 years old at death

Three of them (Nos. 2, 4 and 7) died of chicken diphtheria.

All the inter-breed chimeric birds, males and females, had underdeveloped sex glands. They all failed to mate. The testes of one White Leghorn–Rhode Island Red male, a strong and hefty bird, which was killed when more than 3 years old, weighed 10·4 g (Fig. 2). When histologically examined, the testes contained a large number of spermatozoa. Motile spermatozoa were also found in the vasa deferentia. In the ovaries of female

Table 1

	Type of chimera	Sex	Length of survival in days	Body-weight (g)	Weight of sex glands (g)	Cause of death
(1)	Barred Rock→Rhode Island Red	Male	70	584 at 2 months		Sharp paroxysmal fits, cause unknown
(2)	White Leghorn→Rhode Island Red	,,	1,147	3,085 at 9 months 3,600 at 17 months	10·400	Diphtheria
(3)	,, ,, ,, ,,	,,	338		0·410	?
(4)	,, ,, ,, ,,	,,	180	1,695 at 6 months	0·530	Diphtheria
(5)	,, ,, ,, ,,	,,	15			Low viability

(7)	,, ,, ,, ,,	,,	1,240	1,985 at 11 months		Diphtheria
(8)	,, ,, ,, ,,	,,	249	1,350 at 6 months		?
(9)	,, ,, ,, ,,	,,	210	975 at 7 months		?
(10)	,, ,, ,, ,,	,,	22			Low viability

birds, numerous oocytes in the early stages of differentiation were always found. One White Leghorn female, which on 14 consecutive days was given intraorally 500 mg dry-weight calf anterior pituitary, laid one egg only. This demonstrated the capacity of the ovary to react to gonadotrophic hormones.

Three autoplastic birds—one Rhode Island Red male, one Rhode Island Red female, and one White Leghorn female—reached maturity. The Rhode Island Red female laid eggs which in due course hatched, but she also laid a number of very small yolkless eggs. The White Leghorn female laid her first egg when 13 months old. The autoplastic Rhode Island Red male is now 2 years old, but sterile.

Our cursory investigations on the pituitary have shown that this gland, although normal in general appearance, is smaller in chimeric birds than that of the normal bird of corresponding age. As the region from which the primordium which gives rise to the pituitary gland lies close to the plane of transection, it is reasonable to suppose that its development must have been affected by the operation.

Although a majority of the inter-breed chimeric birds which hatched died in the early months of life, there was no evidence that an immunity reaction was responsible for their death. Three inter-breed chimeras, two of which died when more than 3 years, and another, still alive at 5 years of age, prove conclusively that, barring accidental death and the consequences of imperfect operation, these animals are capable of living their normal life-span.

All the inter-breed compound birds failed to show mating instinct. In all of them the sex glands were underdeveloped to a greater or lesser degree. We think that in both the inter-breed and autoplastic animals the imperfect development of the pituitary gland is the primary cause of the hypofunctional state of the sex glands.

Fixation of Parental Strain Lymphocytes in F_1 Hybrid Rats during Cross-circulation

IT is now well established that homologous disease follows the injection of immunologically competent cells into new-born animals[1–3], F_1 hybrids[4,5], irradiated animals[6] and adult animals rendered tolerant by neonatal injections of lymphoid cells[7], as well as after repeated injection of a large number of lymphoid cells into adults[8]. Peripheral blood lymphocytes have been shown to be immunologically competent, and homologous disease has been produced by the injection of whole blood[9], or buffy-coat layer cells[10]. To reduce the amount of damage suffered by lymphocytes during manipulation *in vitro*, a technique has been developed for cross-circulating the blood between two rats. Using this technique, homologous disease has been produced with the parent–F_1 hybrid combination, and the problem of whether transfused parental strain lymphocytes continue to recirculate in the host after transfusion, or whether they are rapidly fixed in the tissues, has been investigated.

Cross-circulation was established between a rat of a highly inbred 'Marshall' strain and a hybrid rat derived by crossing the 'Marshall' with a second highly inbred 'August' strain. The right common carotid artery and the right jugular vein of each partner were cannulated and the blood flow rate recorded by means of a drop counting device, the flow rate being regulated to about 2/3 ml. per min. After cross-circulation for 1 h, the 'Marshall' rat was taken off and within 15 min a second hybrid rat was cross-circulated with the first hybrid for another hour.

The effectiveness of the cross-circulation was assessed by labelling the red blood corpuscles of the 'Marshall' rat with chromium-51 and measuring the activity of blood samples taken from both rats at repeated intervals. The labelled cells were equally distributed between the 'Marshall' and first F_1 hybrid, and again between the first and second F_1 hybrid within 1 h of starting cross-circulation (Fig. 1).

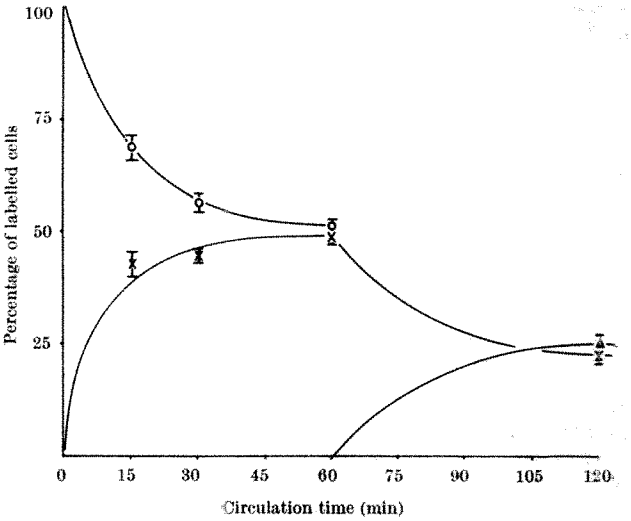

Fig. 1. Distribution of ^{51}Cr-labelled red cells between 'Marshall' (○), first F_1 hybrid (×) and second F_1 hybrid rats (△). The number of labelled cells in each animal as a proportion of the labelled cells initially administered to the 'Marshall' rat was calculated, assuming 6·3 ml. of blood per 100 g body-weight (ref. 11)

The spleen weight on the ninth day after cross-circulation was taken as a measure of the effectiveness of the peripheral blood in producing homologous disease[2]. Table 1 gives the results of such experiments. It is seen that cross-circulating a 'Marshall' with a hybrid rat for 1 h produces a splenic enlargement in the hybrid from the mean normal weight of 478 mg to 1,362 mg. When this procedure is repeated and the hybrid rat is then cross-circulated with a second hybrid for another hour, it is seen that in the first hybrid the spleen weighs 1,342 mg—which is not significantly different from the previous result—whereas in the second hybrid the spleen weighs only 842 mg. If increment in spleen weight is proportional to dose of 'Marshall' lymphocytes, it may be concluded that the 'Marshall' lymphocytes are distributed in the first and second hybrids in the ratio of 2·4 : 1, so that a large proportion of 'Marshall' lymphocytes are being fixed in the first hybrid during the periods of cross-circulation.

Table 1. SPLEEN WEIGHT FOLLOWING CROSS-CIRCULATION

Rat	No.	Cross-circulation	Spleen weight mg (mean ± S.E.)
Hybrid	6	None	478 ± 23
Hybrid	4	With 'Marshall' only	1,362 ± 32
Hybrid	4	With 'Marshall' followed by second hybrid	1,342 ± 20
Hybrid	4	With first hybrid only	842 ± 53
'Marshall'	6	None	597 ± 25
'Marshall'	8	With hybrid	778 ± 51

From Table 1 it is also seen that the 'Marshall' spleen is slightly, but consistently, enlarged. This is probably caused by an immunological response of the 'Marshall' rat to the foreign hybrid cells.

This work was undertaken during the tenure of a Gordon Jacobs fellowship. I thank Prof. D. W. Smithers and Dr. E. O. Field for their help and advice.

PATHOLOGY

Genome Mutation and Carcinogenesis

It has not as yet been possible to establish a relationship between specific chromosome changes and the origin of malignancy. It is believed that the observations reported in this communication may offer an approach to this problem.

In their report on tumour chromosomes, Makino *et al.*[1] included tables giving the chromosome complements of single tumours. The chromosome complements of three female gastric carcinomata of the effusion type were recorded in this way.

Calculations on the heterogeneity of the complements of each tumour cell population showed that the individual data of these three tumours can be pooled[2]. After the complements had been arranged according to their total number of normal chromosomes, χ^2 values were calculated to test whether the total number of chromosomes of the complement influenced the distribution of the chromosomes over the nine groups of the Denver classification. The data presented in Table 1 show that it does not. The chromosome complements of the cells within the same tumour are characterized by a surprising homogeneity; χ^2 values have probabilities greater than 99 per cent.

Table 1. Homogeneity in the Distributions of Chromosomes over the Nine Groups of the Denver Classification, within Three Tumour Cell Populations*

Tumour	Total No. of chromosomes	Degrees of freedom	χ^2	P
Gs-53	3,592	56	25·58	$0{\cdot}995 < P < 1{\cdot}000$
Gs-54	1,880	24	10·05	$0{\cdot}990 < P < 0{\cdot}995$
Gs-42	763	8	1·54	$0{\cdot}990 < P < 0{\cdot}995$

* The cells were arranged according to increasing chromosome numbers and pooled in groups of six or seven.

When the pooled numbers for each group were compared with the numbers expected on the basis of the normal chromosome complement, striking differences were observed in some groups, while others showed perfect correspondence. The results are presented in Table 2. They indicate that in tumour *Gs*-53 five groups were normal and four abnormal. The results for tumours *Gs*-54 and *Gs*-42 reveal a similar phenomenon, that is, there are pronounced deviations in certain groups, while others show no significant difference. Each tumour is thus characterized by its deviating groups.

In tumour *Gs*-53 the deviations can be grouped in two parts. The number of chromosomes found in groups A_3 and G deviate by 54·8 and 47·4, respectively, from their expected values, and the number found in groups B and D deviate by 169·6 and 163·5.

On account of these characteristics of the tumour cell population—specific deviations of the tumour chromosome groups from the normal pattern, regularity in the extent of the deviations and the statistical homogeneity within the tumour—each of these tumours may be considered to be a clone, derived from a cell with an abnormal chromosome complement.

On this assumption, the number of chromosomes in each group of the abnormal chromosome complement can be estimated. As the modal number of tumour chromosomes usually approaches the diploid, triploid or tetraploid chromosome number, the stem cell from which the tumour originates should be about diploid, triploid or tetraploid. Since the 57 cells of tumour *Gs*-53 show that this tumour is near triploid (modal chromosome number of 62), it is believed that the stem cell of this tumour was triploid or nearly triploid. The figures estimated on this assumption for the nine chromosome groups are given in Table 3. Their total number, however, is 68 instead of 69. With a total of 68 chromosomes, a new estimate of the chromosome number per group was made. The data then showed a good fit with whole numbers.

A similar result is obtained when this kind of analysis is applied to the 27 cells of tumour *Gs*-54 (modal chromosome number(s) in the range of 68–72). Here the most likely number of chromosomes is 70 (see Table 3). As the total number of chromosomes of tumour *Gs*-42 is only 763, derived from thirteen metaphase plates, it is not possible to make a reasonable estimate of the underlying chromosome complement for this tumour. Of course it is not possible to be certain that the estimates of 68 chromosomes for tumour *Gs*-53 and of 70 for tumour *Gs*-54 are correct. When another number, for example the modal chromosome number, is taken as the original number of chromosomes, a slightly different chromosome complement is obtained. The figures in Table 4 show, however, that 68 and 70 are the most likely chromosome numbers, for these give the best fit with whole numbers, as indicated by the χ^2 values for the goodness of fit; these are smallest when the fit with whole numbers is best. Although this method permits the choice of a total

Table 2. Deviations of the Tumour Chromosome Groups from the Normal Chromosome Complement

Tumour		Chromosome groups

Table 3. Estimation of the Chromosome Complements of the Pseudotriploids, assumed to be the Origin of Tumours *Gs*-53 and *Gs*-54

	No. of chromosomes in the group									Total
	A_1	A_2	A_3	B	C	D	E	F	G	
Normal triploid	3	3	3	6	24	9	9	6	6	69
Tumour *Gs*-53										
Estimated Nos. when total is 69	3·2	3·1	4·1	9·2	24·4	5·9	8·4	5·6	5·1	69
Chromosome complement in whole Nos.	3	3	4	9	24	6	8	6	5	68
Estimated Nos. when total is 68	3·2	3·0	4·0	9·1	24·0	5·8	8·3	5·6	5·0	68
Tumour *Gs*-54										
Estimated Nos. when total is 69	2·6	5·5	1·2	4·1	25·7	8·6	10·1	6·0	5·3	69
Chromosome complement in whole Nos.	3	6	1	4	26	9	10	6	5	70
Estimated Nos. when total is 70	2·6	5·6	1·2	4·2	26·1	8·7	10·3	6·0	5·3	70

For an estimation of the No. of chromosomes in a group of the pseudotriploid, the total number of chromosomes found in this group is divided by the number, which is representative for one chromosome. For example, when the total No. of chromosomes of the pseudotriploid is 69, the estimation of the No. of chromosomes in group A_1 of tumour *Gs*-53 is $= 169 : \frac{3,592}{69} = 3{\cdot}2$ (3 in whole numbers).

Table 4. Goodness of Fit for Testing the Most Likely Total No. of the Abnormal Chromosome Complement

Total No. of chromosomes	61	62	63	64	65	66	67	68	69	70	71	72	73	74	75	76
Tumour *Gs*-53	10·55	8·33	7·52	6·65	5·02	4·22	4·30	3·54	4·35	4·76	5·27	—	—	—	—	—
Tumour *Gs*-54	—	—	—	—	—	—	5·40	4·88	4·62	4·34	4·83	4·97	4·65	4·81	5·18	5·19

The expected No. for the goodness of fit has been calculated in the following way: $\frac{\text{Total No. of chromosomes}}{\text{Total No. of abnormal chromosome complement}} \times$ estimated No. in group. For example, when the total No. in the chromosome complement is 69, the expectation of group A_1 of tumour *Gs*-53, is $= 3,592/69 \times 3 = 156{\cdot}2$. With the aid of these expectations χ^2 values were calculated.

chromosome number, it is not known how far this choice is reliable.

The mechanism through which a cell with such an abnormal chromosome complement would arise still remains obscure. Possibly an abnormal mitosis with many simultaneous non-disjunctions can account for this.

Abnormal chromosome complements might also arise when the chromosomes of polyploid cells segregate, as indicated by experiments with fused hybrid cells[3]. Another mechanism with disturbing influence may be the endoreduplication of chromosomes[4]. Of course it cannot be ruled out that these tumours arose by gradual selection of many abnormal karyotypes or by gradual selection of clones within a tumour cell population[5].

The present findings, however, agree with Boveri's original hypothesis[6]: as early as 1914, Boveri proposed that tumours could originate by an abnormal chromosome complement. Multipolar divisions were assumed to be the origin of this kind of aberration. It is of interest that Boveri assumed that a large variation in chromosome counts in an otherwise uniform tumour should invalidate his hypothesis—it is precisely this variation that has concealed the underlying abnormal pattern.

The present results give support to the idea that a tumour cell population can sometimes develop out of a cell with a genome mutation. Such cells have occasionally been reported. Buckton *et al.*[7], for example, in their classification of aberrant cells, recorded such aberrations from the normal pattern in C_3 cells. As an explanation they suggested inversions, deletions and translocations. This kind of aberration is found in leucocytes after X-irradiation and these cells may persist for years. Such cells were also found by Visfeldt[8] in cultures of human skin fibroblasts after irradiation. Likewise, a diploid cell from bone marrow was recorded with one chromosome missing in groups 13–15 and one additional chromosome in groups 17–18.

Why these cells should develop into a clone of tumour cells is not clear. It is possible that the abnormal chromosome constitution disturbs the cell control mechanisms. It is possible that interference with cell differentiation results in cell proliferation.

Chromosomes and Cancer

Ishihara *et al.*[1] have recorded detailed data on the chromosomal analysis of twenty human female tumours of the breast, ovary and colon. Further calculations on their data have revealed some interesting features concerning the distribution of the chromosomes over seven groups of the Denver classification. For this purpose we used the data given in Table 4 of the report by Ishihara *et al.*[1]. These data were converted into percentages, that is, the distributions of the chromosomes over the groups were expressed as a percentage of the total number of normal chromosomes per cell. This was the same method as was used by Galton *et al.*[2], except that, in order to facilitate a comparison between the normal human chromosome complement and that of the tumour cells, I excluded abnormal chromosomes from all calculations. (It should be noted that the exclusion of the abnormal acrocentric chromosomes[1,3] from all calculations does not affect the present conclusion.)

In a number of cases, Ishihara *et al.* gave two stemlines for one patient; when this was so, the lowest and highest number of chromosomes in each group were counted together and percentages computed for these numbers.

The results of these calculations are given in Table 1, and it can be seen that no tumour resembles another with respect to its chromosomal distribution. However, by

comparing the chromosomal distributions of all tumours with those of normal cells, it can be seen that in the majority of tumours, group *C* has more chromosomes, whereas groups *D* and *G* both have fewer chromosomes than normal. These discrepancies can be interpreted if it is assumed that reciprocal translocations are formed between the acrocentric chromosomes of group *D* and those of group *G*, and this produces small fragments and submetacentric chromosomes, indistinguishable from the chromosomes of group *C*. This idea is supported by the finding that the nucleolus in human cells is formed by nucleolus organizers located on the short arms of the acrocentric chromosomes[4,5] and, according to Ohno *et al.*[6], these chromosomes are more liable to undergo breakage. Moreover, 'minutes' form a considerable proportion of the abnormal chromosomes of the tumours described by Ishihara *et al.* Further evidence is obtained by calculations on the data given by Makino *et al.*[3]. The data given by Makino *et al.* in their Table 2 (concerning gastric tumours of male and female origin) were converted in the same way as those of Ishihara *et al.* Abnormal chromosomes and tumours possessing a normal chromosome complement were excluded from all calculations. For the tumours *Gs* 42, *Gs* 53 and *Gs* 54 the mean percentages were calculated with the aid of Tables 3, 4 and 5 of Makino *et al.*, respectively. This was done after it had been demonstrated that the distribution of the chromosomes over the groups was the same, irrespective of the number of chromosomes present.

A comparison of the chromosomal distributions of all tumours with those of normal cells (Table 2, this communication) shows that in the majority of tumours, originating from both males and females, group *C* has more chromosomes than normal, but that both groups *D* and *G* have fewer. These observations are in good agreement with those made from the data of Ishihara *et al.* 'Minutes' also form a considerable proportion of the abnormal chromosomes described in the publication of Makino *et al.*

In addition, the data given here in Tables 1 and 2 have been tested by Cochran's test. For this purpose the percentages of each group of all tumours were compared with the normal percentages. The differences found were recorded as '+' if the percentage of the tumour group was higher than that of the normal, as '−' if the percentage of the tumour group was lower than that of the normal, and as 'O' if there was no difference between the two percentages.

The results of this test are shown in Table 3. It can be seen from these results that the signs are not randomly distributed over the groups. Thus group *C* has a preponderance of positive signs, while the opposite trend is observed for both groups *D* and *G*. This finding therefore supports the interpretation already given. Nevertheless it is possible that this trend does not come to light in a particular tumour as a consequence of other changes.

Table 3. Cochran's Test Applied to the Data of Tables 1 and 2. The O Signs had been Added Arbitrarily to the '+' Signs

Group	*A*	*B*	*C*	*D*	*E*	*F*	*G*
Sign O	1	1	—	—	—	2	—
Sign +	14	12	22	4	14	12	5
Sign −	11	13	4	22	12	12	21

$Q \approx X_{(6)} = 32{\cdot}16$ $P \approx 0{\cdot}00002$

In conclusion, it can be stated that the formation of reciprocal translocations involving the acrocentric chromosomes (groups *D* and *G*) may help in interpreting the abnormal chromosome complement of widely different tumours.

Regulation of Leucocyte Alkaline Phosphatase and the Philadelphia Chromosome

IN recent years there has been a number of reports concerning the relationship in the human cell between chromosome 21 and leucocyte alkaline phosphatase (LAP)[1-3]. It has been suggested that, since the LAP was elevated in trisomy 21 and lowered in chronic granulocytic leukaemia (CGL) in which the Philadelphia (Ph^1) chromosome was present, the structural gene for LAP was located on the distal one-third of chromosome 21. The changes of LAP in these diseases were in the proper direction and a gene-dose effect seemed plausible.

However, in a case of chronic granulocytic leukaemia with the Ph^1 chromosome[4], it was shown that elevated levels of leucocyte alkaline phosphatase could occur. In addition, Mellman *et al.*[5] demonstrated that in the presence of an extra chromosome 21 of mongolism, excessive amounts of protein (enzyme) were produced even of *X*-linked genes. These reports were strong evidence against location of the structural gene for leucocyte alkaline phosphatase on the distal one-third of chromosome 21.

An attempt was made[4] to interpret the results according to the operon concept of Jacob and Monod[6]. The proposal suggested a system involving two regulators, the second of which was called a 'modifier'[7]. The requirement of a series of regulators for the activity of an operon has been well established[8,9].

A formulation of the foregoing situation could be made as follows:

Normal $- 2R_2 + 2R_1 + 2OS \rightarrow$ LAP—normal
CGL with $Ph^1 - 1R_2 + 2R_1 + 2OS \rightarrow$ LAP – decreased

(R_2 is regulator 2 or modifier; R_1 is regulator 1; OS is operator-structural gene complex; LAP is leucocyte alkaline phosphatase).

If the formulation is useful, certain predictions may be made with respect to LAP-levels with changes in the number of chromosome 21 or the Ph^1 chromosome.

In CGL with two chromosomes 21 and a Ph^1 chromosome (47 chromosomes with four normal *G*-group chromosomes and one Ph^1 chromosome), the control mechanism may be written as follows: $2R_2 + 2R_1 + 2OS \rightarrow$ normal LAP. The LAP is expected to be at near normal levels because the regulation would have been returned toward normal, despite the Ph^1 chromosome. In CGL with 47 chromosomes, if the addition to the complement is a second Ph^1, the regulation may be written: $1R_2 + 2R_1 + 2OS \rightarrow$ decreased LAP. The increase of chromosome number has not increased the number of R_2, and thus the status is comparable with the usual case of CGL, 46 chromosomes, one of which is a Ph^1 chromosome.

Two cases of chronic granulocytic leukaemia with two Ph^1 chromosomes have been described recently[10]. One case showed 30 per cent cells with 46 chromosomes, two of which were Ph^1 chromosomes; 70 per cent of the cells had 47 chromosomes including two Ph^1 chromosomes and are suitable for testing the formulation. The LAP was low (0). In the 47 chromosome complement, the second Ph^1 might be considered the 'extra' one. However, as the 46 chromosome cells had two Ph^1 chromosomes, it is probably better considered the 'stem' line from which the 47 chromosome cells arose. If so, there would be no normal chromosome 21 from which the extra *G*-group chromosome might arise. Therefore, the additional chromosome is thought to be a number 22. Consistent with this deduction is the fact that the patient did not develop an elevated LAP despite the acute blastic crisis described by the authors. It is usual that in CGL (with the Ph^1 chromosome) for the LAP to be low except in complications such as acute blastic crisis, when it commonly rises. The failure of the increase in LAP in this case is interpreted as a complete lack of R_2 with uninhibited action of R_1. This would result in more or less complete block of the OS complex.

Corroborating these views is a recent case of CGL seen at the City of Hope Medical Center. The patient, a 39-year-old Caucasian female, had an initial LAP score of 31 (normal 45–90). Cytogenetic investigations were undertaken several months after initial diagnosis when she was hospitalized for an acute blastic crisis. Her marrow showed bimodal, equal distribution of 46 and 47 chromosome cells, each with one Ph^1 chromosome. In the 47 chromosome cell, the addition was in the *G*-group. At least one *G*-group chromosome must have been a 21, since the LAP, tested simultaneously with the marrow study, revealed a score of 290.

The manner in which the modifier might work has not been elucidated. One possibility may be described as follows: the second regulator (or modifier) codes for a protein which combines with an effector (a metabolite or some other small molecule) in the cytoplasm. The resultant molecule may act directly on the R_1 gene or on the product of the R_1 and its effector (R_1-effector). It is the R_1-effector substance which controls the operator. In this way the ratio between R_2-effector and R_1-effector would determine how much R_1-effector could be available for inactivation of the 'operator'. If the modifier gene R_2 were absent on one chromosome (the Ph^1 chromosome), less regulation of R_1 would occur. Therefore, more R_1-effector would be available to inhibit operator and lower LAP.

In mongolism extra quantities of modifier due to trisomy of 21 would provide a more marked inhibition of R_1, so that more of the product of operator-structural genes would be present. Therefore, LAP would be elevated. In trisomy 21, much more is happening than the simple increase of modifier (R_2). The extra chromosome is associated with profound disturbances of metabolism; however, increases of an enzyme may be logically traced to the presence of increased amounts of regulator in the cell. Regulators for other genes may be present on chromosome 21 and, for that reason, elevation of other enzymes would be expected. The report of Mellman *et al.*[5] suggests such an interpretation. The fact that regulator need not be on the chromosome near the structural genes or on the same chromosome has been demonstrated in bacterial systems[6]. If control works at the level of messenger RNA as suggested by Ames and Hartman[11] and others, it is conceivable that the location of the regulator gene may be on chromosomes other than those with the structural genes. Thus, the explanation used for the variation of LAP in the presence of the Ph^1 chromosome may be extended to the data of Mellman *et al.*[5].

Seeming exceptions to the findings predicted by the hypothesis may occur because of effectors which are common to several inductive or repressible pathways. This may explain the elevation of the LAP in CGL when acute inflammatory processes of widespread nature or acute transformation of the leukaemic process occurs. The complexity of the situation in mammalian cells makes it difficult to apply the theory rigidly. Nevertheless, we suggest that a beginning may be made in the understanding of regulatory mechanisms of protein synthesis in the propositions submitted. Some support for the hypothesis is its application to alkaline phosphatase levels in cultured heteroploid cells[12]. In this investigation, alkaline phosphatase was always lowered when the number of chromosomes in the *G*-group was decreased.

This investigation was supported in part by General Research support grant 1SO1 *FR* 05471-03-5, and by a supporting fund established in the name of Daniel E. Conway.

I thank Dr. W. Kaplan and Dr. A. Knudson for advice, and Mrs. M. R. Teplitz, Miss V. Foley and Miss K. Hansson for their assistance.

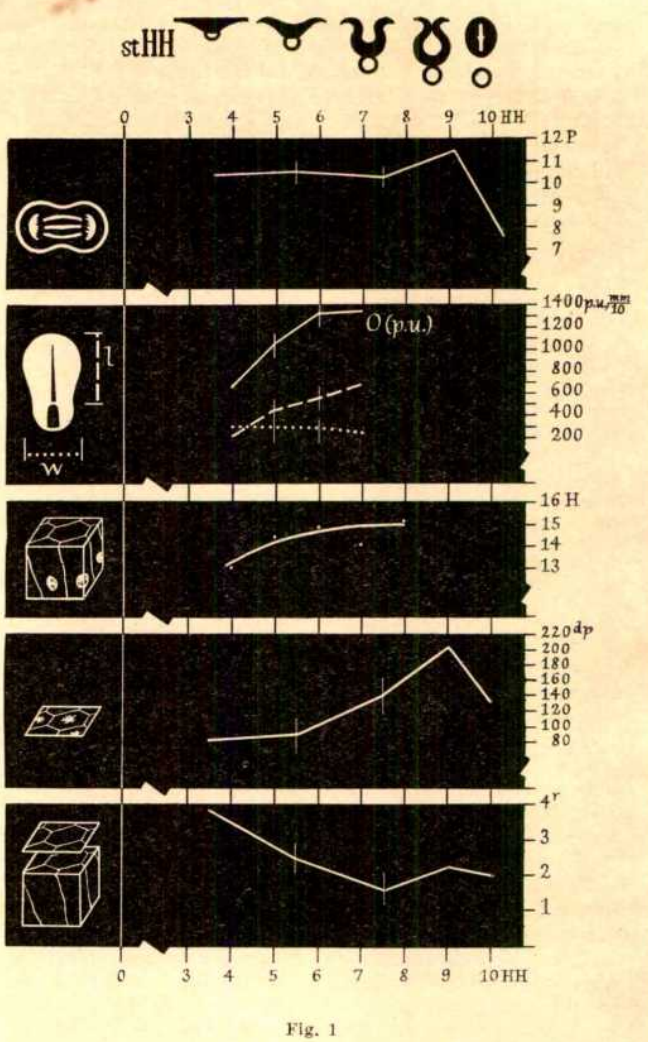

Fig. 1

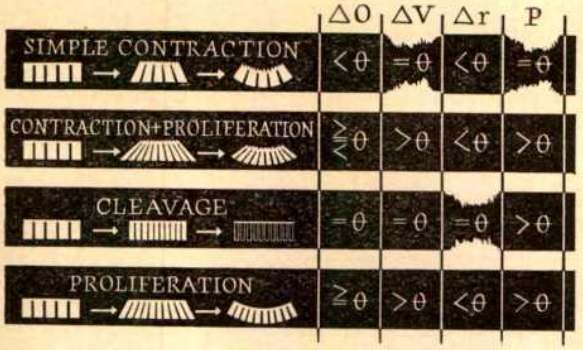
ANATOMY



Influence of Mitotic Activity on Neurulation Movements

According to the present view, the forces responsible for the closure of the neural tube reside in the neural plate itself. On this view, the disproportion between the surface area and the volume of the neural plate is the real mechanical cause of neurulation movements. This disproportion can arise either by a diminution of the surface area, or by an increase in volume, or, occasionally, by a combination of both processes. In all these cases the neural plate cells must be firmly anchored in the developing internal limiting membrane system[1,2]. The first possibility has been generally conceded as the theory of active contraction[3-6], which presupposes the existence of a contractile system settled either extra- or intra-cellularly at the level of the internal limiting membrane. Volume increase of the neural plate may occur either as a result of cell multiplication (proliferation hypothesis), or by an augmentation in size of particular cells (hydration hypothesis[7]). The active part of proliferation has generally been overlooked, in spite of the fact that only one research worker[7] denies the existence of mitoses in the neural plate.

In an attempt to clear up this confusion we measured the quantitative parameters in 115 chick neurulae. A previous series of experiments, in which various noxious factors were placed on the embryo during neurulation, has demonstrated unambiguously that the phase of formation of the neural lips is extremely important for the development of dysraphic malformations of the central nervous system. Our attention was, therefore, focused on this phase. We attempted to discover: (1) Whether mitotic division does occur during neurulation. We found that proliferation does occur, and is higher than in any of the following stages[8] (Fig. 1, *P*). (2) What happens to the surface area of a neural plate. We found that it increases linearly (Fig. 1, 0), due to its lengthening (Fig. 1, *l*). The fact that the width, *w*, of a neural plate does not change at all is contrary to the theory of a mere contraction. As no diminution of the surface extension of a neural plate can be observed, an increase in volume is to be anticipated. Two facts give evidence of this process: (*a*) the steep decline in the surface-volume ratio (Fig. 1, *r*); (*b*) the mirror increase in the number of colchicine-arrested mitoses per square surface unit (Fig. 1, *dp*). On the basis of these data we reject the assumption[9] that, during neurulation, the cells do not attain their original size after being duplicated, and that this process would, therefore, suggest the cleavage of a miolecithal egg. The hypothesis of differential hydration is also endangered[10]. We have shown repeatedly that the number of nuclei per unit volume is increased during neurulation. This fact alone is incompatible with the idea of hydration (Fig. 1, *H*).

Table 1, summarizing our results, shows that both the theory of simple contraction and the 'cleavage' hypothesis cannot be applied to the chick. We thus attempted to determine whether proliferation may be considered an effectual factor in neurulation movements. The following objections to the active contraction, simultaneously taking place, can be raised:

Table 1

(1) On the electron micrographs we have not succeeded in finding a continuous 'contractile' layer in the cytoplasm beneath the cell surface[11]. The denser spots occur in the cytoplasm of cells only in the neighbourhood of, and as an integral part of, desmosomal contacts.

(2) It seems improbable that contraction occurs in harmony with the surface expansion of the neural plate, without its width being altered.

(3) The number of dividing cells increases up to the moment of closure of the neural tube. Obviously this would have a disturbing effect on the continuity of the contractile layer.

(4) Since the proliferation activity remains constant, the number of mitoses per square unit of surface (Fig. 1, *dp*) is proportional to the number of cells anchored in each surface unit of the internal limiting membrane system. Any simultaneous contraction would produce a dramatic change in the curves *dp* and *r*. However, as no phenomenon of this type occurs, the proliferation activity may be considered as the main dynamic factor of neurulation movements, the static factor being the firm anchoring of the neural plate cells in the developing internal limiting membrane system.

RADIOBIOLOGY

Induction of Chromosome Injuries in Mouse Bone Marrow under the Distant Effect of Ionizing Radiation

DESTRUCTIVE processes are known to be absent from shielded regions of the haemopoietic system but present in irradiated regions[1,2]. Yet it has been shown that shortly after irradiation the concentration of deoxyribonucleotides and nucleosides decreases. This is followed by a decrease in DNA in the cells of both irradiated and shielded regions of the bone marrow[3,4]. DNA synthesis has also been found to be inhibited not only in irradiated but also, to a somewhat lesser degree, in shielded tumours[5,6].

The question of the distant effect of radiation on the appearance and character of chromosome injuries is still open. The distant effect of radiation of the chromosome apparatus has been described for plant cells, where true chromosome rearrangements were observed[7–9]. There are also some data indicating that shielded mammalian tissues, such as the corneal and skin epithelium, do not show significant increase in the number of chromosome aberrations when compared with normal ones[10–12].

In the present communication we present an attempt to study the data on the distant effect of ionizing radiation on the chromosome in bone marrow cells.

Experiments were carried out on male and female mice of the *C57BL* strain weighing 18–20 g. The irradiation factors were as follows: X-ray machine of *RUP*-1 type; 210 kVp., 15 m.amp, filtration 0·75 mm Al + 0·5 mm Cu, dose rate 50 r./min. The animals were divided into three groups In the first group only one hind limb was irradiated with 700 r., all other parts of the body being shielded; in groups 2 and 3 surgically exteriorized intestine was irradiated with 700 or 3,000 r., the body being shielded. A 5–8-mm lead plate was used as a screen. Under these conditions the shielded parts of the body received 0·2–0·5 per cent of the total dose.

The animals were killed 2, 6, 24, 48, 72, and 120 h after the exposure to radiation (4–7 mice for each point). The femurs of the shielded limbs were fixed in Carnoy's solution. Bone marrow pieces were totally stained using Feulgen and light green stains, and squashed. Cells with chromosome injuries were counted at the stages of late anaphase and early telophase. About 100 cells at these stages were counted in each animal.

The percentage of bone marrow cells with chromosome damage in unirradiated mice was equal to 8·1 ± 0·4 per cent, whereas the proportion of cells with chromosome bridges only was 6·40 ± 0·8 per cent.

When only one hind limb was exposed to radiation, a distinct increase in the number of cells with chromosome injuries was found in shielded regions of the bone marrow (Table 1). In directly irradiated limbs, the percentage of cells with chromosome aberrations was 97·3 ± 0·9, 83·7 ± 4·4, 50·3 ± 6·8 and 18·1 ± 0·7, 6, 24, 48, and 72 h after irradiation, respectively.

Chromosome damages in the shielded bone marrow cells were not a result of direct irradiation. These cells were given no more than 3·5 r., but the total body X-irradiation with 7 and 15 r. induced only 10·0 and 11·4 per cent respectively of cells with chromosome aberrations 6 h after treatment. The majority of injured cells had bridges only (7·5 and 10 per cent, respectively). Thus, alterations found in the cells of the shielded bone marrow are due to the distant effect of radiation.

The distant effect also becomes manifest when an irradiated limb is removed 2 h after exposure. When the irradiated limb is removed 8–15 min after exposure, the number of chromosome aberrations in bone marrow cells does not differ from normal (Table 2). Therefore, humoral factors appearing in the irradiated limb start affecting the cells of the shielded bone marrow some 2 h after irradiation. The question arises whether such chromosome injuries in shielded bone marrow cells can be induced by the influences from other irradiated tissues. The percentage of cells with chromosome injuries in unirradiated bone marrow was about the same 3 days after local treatment of the exteriorized intestine with 700 and 3,000 r. and after local exposure of a hind limb to irradiation with 700 r. (Table 1).

Evidence in support of the humoral mechanism of this phenomenon was provided by experiments using injections of the extracts from irradiated tissues into intact mice. Bone marrow cells were destroyed by freezing three times in liquid nitrogen, then thawed and centrifuged at 6,000 r.p.m. The extracts from the intestine were prepared in the following manner. A part of the small intestine was carefully washed with saline solution with the addition of penicillin and streptomycin and then with pure saline solution; thereafter it was homogenized and centrifuged

Table 1. Percentage of Cells with Chromosome Injuries in Shielded Bone Marrow

Time after exposure (h)	Kind of treatment					
	Irradiation of one hind limb with 700 r.		Irradiation of the exteriorized intestine with 700 r.		Irradiation of the exteriorized intestine with 3,000 r.	
	Total No. of cells with chromosome injuries	Cells with bridges only	Total No. of cells with chromosome injuries	Cells with bridges only	Total No. of cells with chromosome injuries	Cells with bridges only
2	—	—	24·9 ± 0·9	22·6 ± 1·4	27·6 ± 0·8	25·3 ± 0·7
6	14·3 ± 1·9	13·1 ± 2·4	—	—	—	—
24	20·8 ± 2·1	18·6 ± 2·9	25·7 ± 3·8	23·2 ± 5·0	24·3 ± 5·2	19·2 ± 5·4
48	27·9 ± 1·3	26·8 ± 1·0	22·3 ± 1·1	21·1 ± 1·2	19·7 ± 2·6	17·2 ± 3·2
72	19·4 ± 4·6	18·7 ± 4·3	20·7 ± 0·9	19·4 ± 1·0	24·8 ± 4·1	24·2 ± 4·0
120	13·0 ± 2·0	13·0 ± 2·0	—	—	—	—

at 6,000 r.p.m. All these procedures were performed on ice and took 2 h. There were no whole cells or nuclei in the extracts obtained with this method. For the preparation of extracts, bone marrow and intestine were taken 2 h after total body irradiation. The extracts, 1 ml. per mouse, were injected into intact animals either intravenously or intraperitoneally, and bone marrow was fixed 2 h after the injection.

Table 3 shows that after an injection of the extracts from normal unirradiated tissues, the percentage of bone marrow cells with chromosome injuries does not differ from the normal one. When extracts from irradiated tissues are injected, the number of injured cells is 18·3 per cent and 21·9 per cent for the intestine and bone marrow extracts, respectively.

A cytological analysis showed that chromosome injuries observed in the cells of both the shielded and intact bone marrow (after an injection of the extracts from irradiated tissues) were represented mostly by chromosome and chromatid bridges (80–90 per cent) (Table 1) apparently formed as a result of stickiness.

The stickiness of irradiated chromosomes is known to be caused either by the depolymerization of DNA[13,14] or by a change in the structural organization of nucleoproteids[15,16]. Irrespective of which hypothesis is valid, the stickiness observed in our experiments may be associated with the changes in DNA concentration[3,4] and with a depression of DNA synthesis[5,6].

The data presented lead us to the conclusion that chromosome injuries appear not only in directly irradiated but also in shielded regions (mostly bridges) of the haemopoietic system. They are induced by humoral influences (observed not earlier than 2 h after exposure) from irradiated tissues. This is proved by the appearance of chromosome damage in the bone marrow cells in the same numbers and at the same time both with local irradiation of the small intestine and with injection of the extracts from the bone marrow or the intestine of irradiated mice into intact unirradiated animals.

Table 2. Percentage of Cells with Chromosome Injuries in Unirradiated Bone Marrow 6 h after Irradiation

Kind of treatment	6 h after irradiation	
	Total No. of cells with chromosome injuries	Cells with bridges only
Body shielded, one hind limb locally irradiated with 700 r. and amputated 2 h after irradiation	22·6 ± 0·5	21·8 ± 0·5
Body shielded, one hind limb locally irradiated with 700 r. and amputated 8–15 min after irradiation	8·4 ± 1·1	7·4 ± 0·8

Table 3. Percentage of Cells with Chromosome Injuries in Bone Marrow of Mice 2 h after Injection of Extracts

Injection of extracts	Total No. of cells with chromosome injuries	Cells with bridges only
Intact intestine	9·3 ± 0·5	9·2 ± 0·5
Intestine irradiated with 3,000 r.	18·3 ± 2·1	17·0 ± 1·5
Intact bone marrow	9·6 ± 0·6	9·6 ± 0·6
Bone marrow irradiated with 700 r.	21·9 ± 1·3	20·7 ± 1·0

Influence of Sodium Salicylate on Radioactive Strontium Retention in Rat and Mouse

This communication reports a programme of test procedures to determine a satisfactory therapy for elimination of radioactive strontium from experimental animals. During the first hour following intraperitoneal administration, the isotope is still amenable to attack and we believe that intravenous sodium citrate is the most effective therapeutic agent[1]. At later times, as the isotope becomes progressively associated with skeletal tissue, citrate is ineffective and the problem of reducing body burden becomes one of improving the excretion over prolonged periods. Sodium salicylate was tested in this connexion in view of its evident pharmacological activity, its possible chelating properties and its low toxicity. Doses were calculated on the maximum recommended human dose.

Fourteen adult Sprague–Dawley rats, female, weight 200 g, were pre-medicated to establish an effective therapeutic concentration by intraperitoneal injection of sodium salicylate (200 mg/kg) for 4 days prior to administration of strontium-85. Each animal was then injected intraperitoneally with 1 μc. strontium-85 and daily salicylate treatment continued thereafter. Fig. 1 shows the cumulative urine and total excreta levels for the 23-day period following injection of the radioactive strontium compared with a control group of animals.

Ten adult *ASL* mice, female, weight 20 g, were also treated with salicylate (200 mg/kg) by oral administra-

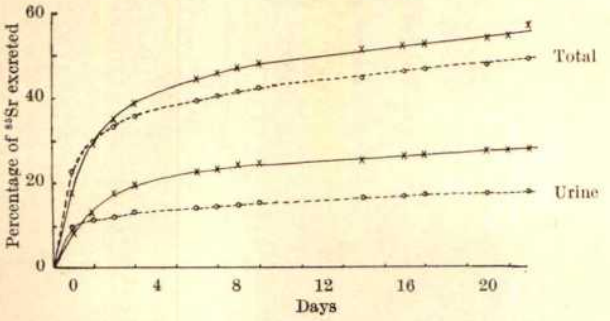

Fig. 1. Cumulative urinary and total excretion of strontium-85 from control (○) and salicylate-treated (×) rats

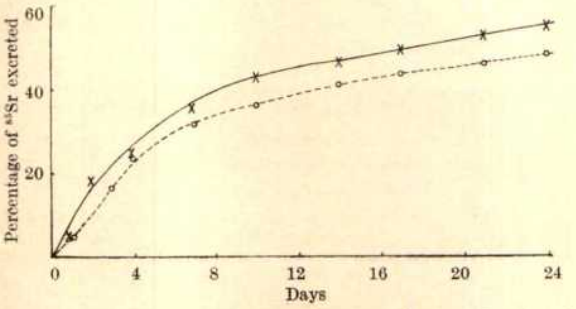

Fig. 2. Cumulative excretion of strontium-85 from control (○) and salicylate-treated (×) mice

tion in drinking water. After 7 days each animal was given an intraperitoneal injection of 1 μc. strontium-85. Salicylate treatment was continued for a further 24 days. Fig. 2 shows the combined excreta levels compared with control animals.

Table 1. Effect of Sodium Salicylate on Excretion of Strontium-85 from Female Rats expressed as Ratios of Amounts from Treated Animals to Amounts from Controls at Periods following Administration of the Isotope

Period (days)	Urine ratio	Faeces ratio
0–1	0·89	0·69
1–2	3·26	1·08
2–3	3·75	1·03
3–4	3·51	0·88
4–7	2·20	1·13
7–8	2·01	0·96
8–9	1·57	1·10
9–10	1·66	0·99
10–15	1·37	1·20
	Rest period	
15–17	0·74	0·68
17–18	1·38	0·96
18–21	1·60	0·80
	Rest period	
21–22	1·12	0·61

The effectiveness of salicylate in improving excretion of radioactive strontium is thus established in rats and mice. The salicylate does not appear to be maximally effective until 48 h have elapsed, which would indicate that salicylate is not playing the part of a chelating agent. Since a diuresis was observed, it is suggested that renal tubular resorption processes are affected. Renal output of strontium-85 from treated animals is increased after 24 h. The ratio of the levels of activity in excreta from treated rats relative to those from controls (Table 1) indicates an improvement in renal output by a factor greater than 3, while the faecal output is unchanged. Furthermore, a preferential excretion is maintained for several days, is lost after withdrawal of salicylate treatment and is restored again after further treatment.

BIOLOGY

Degradation of Arci in a Fossil *Alnus* Pollen Grain

Recognizable biological degradation of fossil Tertiary palynomorphs has generally been limited to or most evident on structurally simple or smooth-walled pollen or spores[1]. Moore[2–5] described the effects of microbiological attack on Palaeozoic fossils and also noted that "some degree of selectivity of the saprophyte upon the host is demonstrated, and the structural features of the various spores are shown to exert considerable control over the distribution and manner of attack; the organism follows these features to a great extent. In spores where there is no marked structural differentiation the ornament of the exine, particularly in thick-walled forms such as *Convolutispora* (p. 364), plays an important part in controlling the distribution of the attack and the manner in which it is carried out"[6].

Goldstein[7], using extant pollen and spores as bait, observed that saprophytic phycomycetes attack different plant groups unequally. The difference in susceptibility may be due to variations in the chemistry of pollen and spore exines from one plant group to another. Various exine layers within a plant group may have different chemical composition[8]. It follows that layers of exine restricted in distribution over the pollen or spore, that is, ornamentation, might reflect differential chemical characteristics.

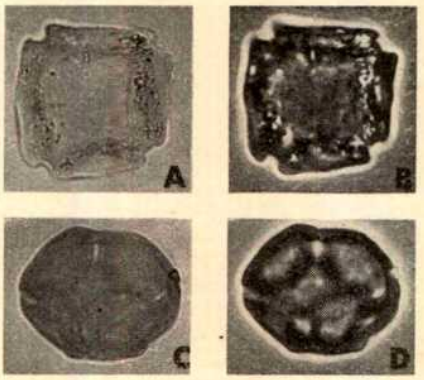

Fig. 1. Photomicrographs of fossil *Alnus* spp. pollen. *A–B*, Exhibiting biological or physico-chemical degradation of the arci; *A*, median focus under bright field; *B*, median focus, phase [contrast (× 1,000). *C–D*, Well-preserved grain with no apparent degradation; *C*, bright field; *D*, phase contrast (× 1,000)

A Tertiary *Alnus* pollen grain exhibiting marked degradation along the arci is further evidence of selective attack on the host (Fig. 1*A–B*). The causative nature of the degradation, whether biological or physico-chemical, remains unknown. It is believed, however, that the presence of the arci controlled the distribution of the process.

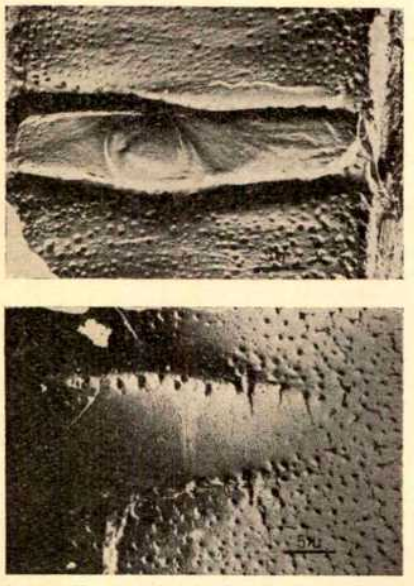
Wall Thickening in *Callitris glauca* R. BR.

Some species of the genus *Callitris* exhibit in varying degrees a special type of thickening of the cell wall in the vicinity of the bordered pits of tracheids. This 'callitroid thickening' (Fig. 1) is diagnostic, and was noted by Patton[1] and was also described by Jane[2].

Cronshaw[3] examined these thickenings in the electron microscope, and was able to show that the 'awns' which appear to project into the cell lumen, were in fact attached along their length to the radial walls, the thickenings usually tapering off in thickness towards the tangential wall.



Carbon replicas of the inner surface of tracheids show that the wart structure[4,5] extends across the thickenings towards the pit aperture, but while the warty membrane persists the warts themselves tend not to occur within the confines of the area delimited by the thickenings. This area is more or less rectangular in shape (Fig. 2), but with a tendency for the thickenings to be closer to one another where they merge with the tangential wall. In tangential longitudinal sections, the thickenings can be seen to arch out over the pit aperture (Fig. 3), giving the appearance of a double border.

Ultra-thin cross-sections have recently been prepared from the xylem of *Callitris glauca* (Fig. 4) and it can be seen that the thickenings are caused by extensive eccentric

Fig. 2. *C. glauca*. Electron-micrographs of carbon replicas of the lumen sides of a radial wall (*a*) and a tangential wall (*b*), showing the extent of the thickenings. Note the wart structure which tends to disappear within the confines of the thickenings

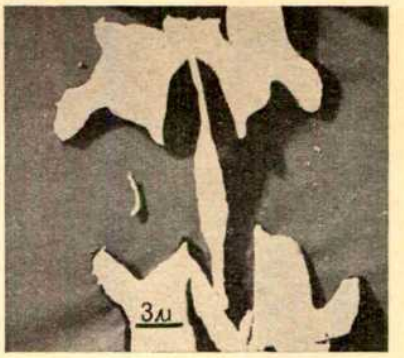

Fig. 3. *C. glauca*. Electron-micrograph of a thick tangential longitudinal section shadowed with platinum–palladium, showing the thickenings arching over a pit and giving the appearance of a double border

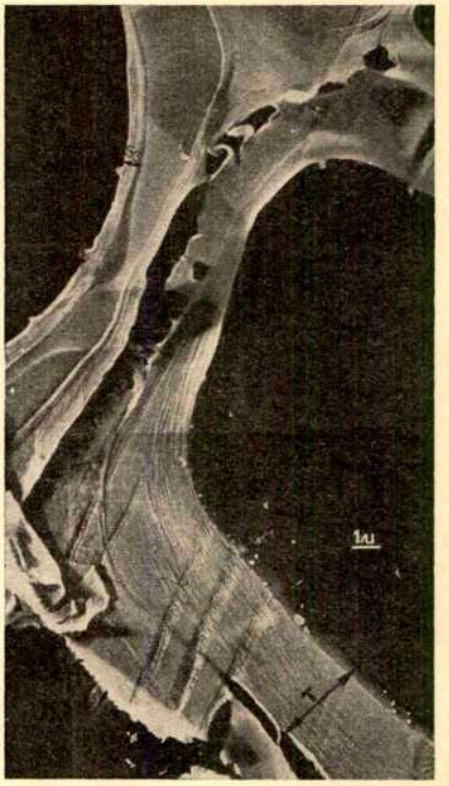

Fig. 4. *C. glauca*. Composite picture of electron-micrographs of a cross-section shadowed with platinum–palladium, showing the extremely thick S_2 layer (*T*) on the radial wall, compared with the normal thickness of S_2

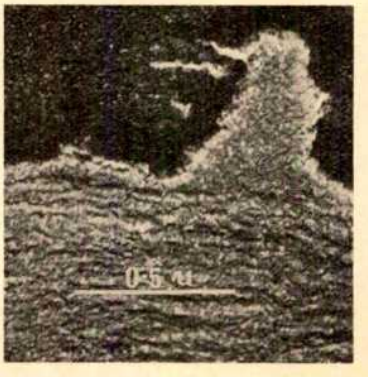

Fig. 5. *C. glauca*. Electron-micrograph of a cross-section through part of the thickened S_2 layer and including a wart

growth of the innermost layer of the secondary wall, generally known as the S_3 layer, as was suggested by Wardrop[6]. The thickest layer of the secondary wall is normally the S_2 layer, consisting of 30–150 lamellae[7], whereas the S_3 layer is normally much less than 30 lamellae. In callitroid thickenings, however, the S_3 layer is about twice the thickness of the S_2 layer.

A highly magnified section through the wart structure is illustrated in Fig. 5. The wart structure has been described by Wardrop and Davies[8] as a localized thickening of the cell wall in the form of a papilla. While this description is in general verified by Fig. 5, it can be seen that the wart itself has a different structure from the S_3 layer. It can be concluded, therefore, that the wart itself is not simply an extension of the S_3 layer. Examinations of other *Callitris* spp. are being carried out.

Genetics of Cuckoo Egg Polymorphism

Recent work on avian chromosomes has opened new vistas in the investigation of egg polymorphism in cuckoos. The question of how some of the parasitic cuckoos can consistently parasitize several unrelated host species in one area, usually with eggs well-matched to those of each host[1–3], has long puzzled biologists. Speculations on the genetics involved have been undertaken by Miller[4] and Punnett (in Chance[2]) among others; these need reappraisal in the light of newer ideas and discoveries.

Punnett (*loc. cit.* and ref. 5) discussed among other possibilities that of *Y*-inheritance, and remarked that it would fail to account for the marked deviations from perfect mimicry known to occur in the case of the common cuckoo (*Cuculus canorus*)[3]. With due regard for Occam's Razor and modern cytogenetic knowledge, it is here proposed that the simple *W*-chromosome (to use the modern *Z*–*W* terminology for avian sex chromosomes) inheritance hypothesis is probably correct. The first positive identification of a *W*-chromosome in birds was reported in 1963 for the budgerigar (*Melopsittacus undulatus*)[6]. Recent work at the City of Hope Medical Center, Duarte, California (unpublished), has disclosed the presence of a large *W* in a Passerine species. Ohno *et al.* have shown that macrochromosomes are remarkably uniform in the avian sub-class Carinatae[7]. Hence it is likely that cuckoos will be found to possess a *W*-chromosome in the heterogametic (female) sex, a highly conjectural possibility prior to 1960 (when all the speculations on cuckoo inheritance occurred).

It is suggested therefore that *W*-inheritance can explain all observed polymorphic phenomena in *C. canorus* specifically, and in other cuckoo species with similar breeding biologies also. Briefly, some of the arguments involved are as follows:

A female cuckoo of a certain host-specific *gens* (egg-monomorphic tribe within a species)[3] would transmit to all her daughters the same egg-colour gene complex that she herself has. According to the *gens* theory, these daughters would be 'imprinted' to their foster-parent species[2,3]. Each daughter would then continue to lay host-matching eggs in nests of that species regardless of the *gens* of her father. Occasional deviations from this pattern can be explained by (1) crossing over (or translocation) between *Z* and *W*; (2) breakdown of imprinting; (3) lack of proper host nests, and other accidental situations. Any of these could explain the occasional cases of mis-matching cited by Southern[3]. It is possible that cases of more frequent misplacement which apparently occur in some areas[1,3] could be ascribed to breakdown in absolute *W*-linkage. For example, a translocation (or cross-over) between *Z* and *W* involving egg-colour genes could become established and spread through a local population because of imperfect discrimination by the host(s) in that area.

The foregoing seems to apply well to the didric cuckoo (*Chrysococcyx caprius*) in South Africa[8–10], in which species, however, *gentes* have not yet been demonstrated. This common bird should prove very suitable for the interesting task which remains: testing the *W* hypothesis cytologically and genetically.

Localization of Ribonucleic Acid in the Cuticle of Nematodes

The demonstration of esterase enzymes in the cuticle of *Ascaris lumbricoides*[1] indicated that this complex structure was metabolically active. The increase in size after the final moult in many nematodes with consequent growth of the cuticle would imply that some biosynthesis takes place during this period. It has been assumed, however, that such biosynthetic activities occurred in the hypodermis[2]. Here I report the demonstration of RNA in the cortical layer of three parasitic nematodes, *Aspiculuris tetraptera*, *Syphacia obvelata* and *Ascaris lumbricoides*.

Two methods for the localization of RNA have been used, namely the acridine orange method of Bertalanffy and Bickis and Kurnick's methyl green-pyronin *Y* method, both methods as given by Pearse[3]. With the former method, fresh frozen 8μ sections were used, and for *A. tetraptera* and *S. obvelata* it was necessary to embed in 2·5 per cent gelatin before sectioning. Sections were cut on a Pearse–Slee cryostat at −20° C. With Kurnick's method, 6μ paraffin sections of worms fixed in Carnoy's fixative (6 : 3 : 1) for 2 h were used. With both methods, controls were pre-incubated in a solution of ribonuclease type IIA (Sigma Chemical Co.) containing 0·5 mg of enzyme per ml.[3]. The substitution of Fenwick's saline[4], at the same *p*H, for Krebs's Ringer solution had no detectable effect on the intensity of staining with acridine orange. In all the three species examined, only the inner cortex of the cuticle was positive; the reaction was absent in all controls including controls of ascarid material pre-incubated in a solution of RNase previously heated at 90° C for 10 min.

The demonstration of RNA in the inner cortex of the cuticle of these nematodes by two different methods precludes the possibility of artefacts and points to the synthesis of proteins in this layer. Chemical analyses of

the cuticle of *Ascaris*[2,5] and histochemical observations on *Aspiculuris* and *Syphacia*[6] have indicated that a large proportion of the cuticular solids are proteins.

The outer cortex in all the species examined is stabilized by disulphide linkages while the inner cortex stains intensely for sulphydryl groups[6,7]. These observations would suggest that a keratin-like protein is present in the cortex, but the X-ray diagram of this region of *Ascaris* is of the typical collagen type[8]. The matrix layer which lies below the cortex shows close similarities to collagenous structures[6,9], but the interface between the two layers constitutes the so-called fibrillar layer which may not necessarily be a morphological entity[5,6].

Investigations of collagen fibrogenesis have shown that ascorbic acid is required for the process and it has been suggested that this carbohydrate is necessary for the hydroxylation of proline residues[10]. By means of the method of Bacchus[3] for the detection of ascorbic acid, it has been demonstrated that in *Aspiculuris* and in *Ascaris* ascorbic acid is distributed diffusely in the inner cortex. Both ATPase (using Wachstein and Meisel's method) and acid phosphatase (using both the azo-dye coupling technique and Gomori's lead nitrate method)[3] have been located in the inner cortex of the three nematodes. These enzymes are known to participate in the formation of one or other of the structural proteins discussed here. It seems reasonable, therefore, to suggest that the cuticle of nematodes, as distinct from the hypodermis, participates in the synthesis of some of the proteins of which it is constituted. Presumably amino-acids and other smaller molecules necessary for such synthesis of protein macromolecules are supplied from the hypodermis. A fuller report of these investigations, now in preparation, will be published elsewhere.

I thank Dr. D. L. Lee for his interest and critical discussions during this work.

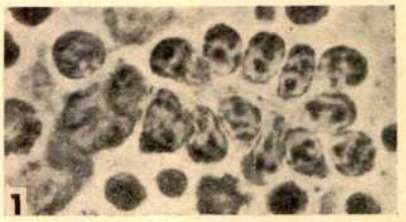
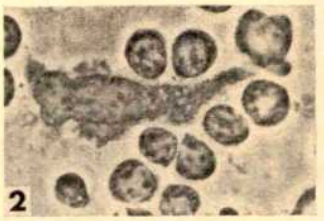
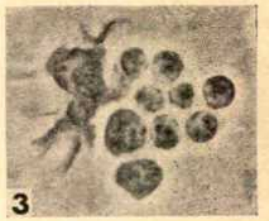
Adhesion of Lymphocytes to Large Motile Cells in Cultures of Rabbit Thymus



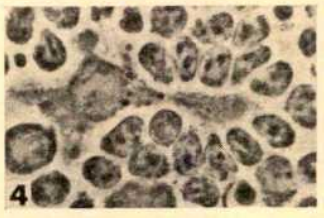
McFarland and Heilman[1] have described the attachment of lymphocytes to macrophages and to transforming blast cells in cultures of leucocytes derived from the mixed venous blood of two unrelated donors. The purpose of this communication is to direct attention to a similar type of association between small lymphocytes and large motile cells, which has been observed repeatedly in cultures of rabbit thymus.



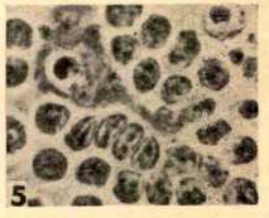
Thymic tissue was taken from healthy rabbits of either sex, their ages ranging from 21 days of foetal life to mature adults, and explanted under 'Cellophane' strips in a modified Rose culture chamber[2]. The chambers were filled with a fluid medium composed of equal parts of pooled rabbit serum and *TC* Medium 199 (Glaxo). After 24 h *in vitro* the explants showed profuse migration of small lymphocytes, together with occasional typical macrophages. In addition, numbers of large motile cells (LMC) were constantly found in the outgrowth, differing in morphology and pattern of movement from the macrophages.



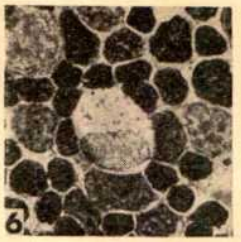
The behaviour of the LMC was recorded by time-lapse cinemicrography on 16 mm film, with the culture chamber on the stage of a phase-contrast microscope enclosed in an incubator maintained at 37° C, and also by a series of still photographs on 35 mm film.



The appearance of a typical LMC is illustrated in Fig. 1; it is an elongated cell, with a broad veil of thin cytoplasm at the advancing edge, behind which lies an irregularly indented nucleus containing one or more nucleoli. Behind the nucleus there is an area of cytoplasm containing granules and small vacuoles, tapering off into a narrow cytoplasmic 'tail'. The time-lapse films reveal that the pattern of movement of LMC is characteristic, with the cytoplasmic veil at the anterior end undergoing rapid undulation; the remainder of the cell preserves a constant shape, with little or no surface activity. The most striking feature of these cells, however, is their ability to carry small lymphocytes which, having become attached to the 'tail' of the LMC, are then dragged along as the motile cell proceeds through the culture medium (Figs. 1–5). Throughout their association with the LMC (which may continue for a period of time varying from several minutes up to 1 h or more) the lymphocytes display a more or less complete cessation of their own normally active movements, remaining entirely passive and adhering to the same point on the surface of the LMC; occasionally a lymphocyte is seen to become detached and is left behind as the LMC moves on. The ultimate fate of such detached lymphocytes is not known, but during the first few minutes following their separation they can be seen to have some surface movement. They do not appear to regain the usual rapid motility of the small lymphocyte, but neither do they show any morphological evidence of impaired viability.



The number of lymphocytes attached to an individual LMC varies from 0 to 10 or more. In one culture chamber, containing 8 explants, 120 LMC were counted, to which were adhering a total of 271 lymphocytes. The frequency of occurrence of the association does not appear to vary with the age of the donor of the thymic explants; it is



Figs. 1–5. Typical examples of the adhesion of small lymphocytes to large motile cells in living cultures of thymus taken from rabbits aged 13 days (Fig. 1) and 10 weeks (Figs. 4, 5) and from a 23-day foetus (Figs. 2, 3). In each case the LMC was moving from right to left. That in Fig. 5 has ingested the pyknotic nucleus of a dead lymphocyte. Phase contrast. (× 740)

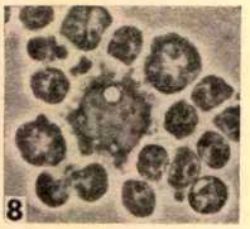


Fig. 6. Close contact between lymphocytes and a large cell with pale, slightly granular cytoplasm. Imprint of thymus, stained May-Grünwald and Giemsa. (× 410)

Figs. 7, 8. Grouping of lymphocytes round cells with irregular nuclei and vacuolated cytoplasm. Fresh, unfixed suspension of cells teased from thymus. Phase contrast. (× 700)

seen as commonly in cultures of thymus from foetal animals as in those from neonatal or adult rabbits, with the qualification that, in mature adults, the thymus tends to be replaced by adipose tissue, with consequent reduction in the numbers of motile cells in the cultures.

If an association of this kind occurs in the intact thymus *in vivo*, and is not merely a result of the abnormal environment of the living cells *in vitro*, it might be anticipated that some evidence of it would be visible in histological preparations; in fact, the density of the cell population in the thymus makes it extremely difficult to recognize such a relationship in stained sections, although Ishidate and Metcalf[3] have reported the congregation of dividing lymphocytes round PAS positive cells in sections of regenerating mouse thymus after cortisone-induced atrophy. However, the examination of stained imprints, or fresh unfixed suspensions, of thymus, in which there is some degree of separation of the cells, indicates that the close association of small lymphocytes with larger cells can be observed quite frequently (Figs. 6–8), suggesting that the events seen in the cultures may indeed take place in the intact thymus *in vivo*.

There is a strong resemblance between the behaviour of the thymic lymphocytes in the cultures described here and the attachment of peripheral blood lymphocytes to other cells depicted by McFarland and Heilman[1]. As these authors have pointed out, this type of contact differs from the active participation of lymphocytes seen in 'emperipolesis'[4] and in 'peripolesis'[5], where they move rapidly around either within the cytoplasm or over the external surface of other types of cell. The lymphocytes, both in the cultures of blood leucocytes and in those of thymus, remain immobile during their period of contact. McFarland and Heilman have suggested that such attachments may permit the transfer of RNA or other substances from cell to cell. The functional interpretation of the contacts between lymphocytes and LMC in the thymic cultures must take into account the nature and origin of the LMC. Judging by their morphology and pattern of movement they are not typical macrophages; furthermore, on the evidence at present available, they do not appear to possess highly developed phagocytic powers; Fig. 5 shows the only example so far encountered of phagocytosis by a large motile cell. The appearance and activity of these cells suggest, if anything, that they may be related to the large lymphocyte. The general appearance, in phase contrast, of the cytoplasm immediately behind the nucleus is compatible with the possession of an active Golgi apparatus; this, coupled with the existence of well-developed nucleoli, leads to the tentative hypothesis that the LMC may be actively synthesizing and secreting a substance, either into the culture medium or directly into the cytoplasm of the attached lymphocytes.

Hydrodynamic Simulation of Small, Passively-sinking Biological Objects

Sinking velocity is an important ecological factor for many small biological objects such as pollen grains, airborne fruits and microplankton. Elaborate structures are often developed to increase drag and reduce sinking velocity, but their effectiveness cannot be directly investigated because of the difficulties involved in manipulation. The hydrodynamics of such small objects can be investigated, however, by using models of convenient size in highly viscous fluids. We have recently used this method in considering the feasibility of a planktonic mode of life for an extinct bivalve mollusc[1] and think the method should interest planktologists, palynologists and others who do not read palaeontological literature.

The flow pattern around bodies sinking steadily in a fluid depends on the Reynolds number $R = \frac{\rho v l}{\mu}$, where ρ = the density of the fluid, μ its viscosity, v the sinking velocity and l (length) a typical dimension. When the Reynolds numbers of the flows around geometrically similar prototype (suffix_p) and model (suffix_m) are the same the flow patterns are also similar. For example, a bivalve mollusc of l_p = 1 mm sinking in water at 1 mm/sec will have a similar flow pattern to a model of l_m = 80 mm sinking in glycerol at about 10 mm/sec.

To find the effect of different drag-producing structures on the prototype they may be simulated on the model and the sinking velocities and immersed weights of the variously modified models found experimentally over a range of viscosities. The equivalent settling velocity of the prototypes in water or air can then be calculated.

When sinking steadily a body experiences a drag force (D) equal and opposite to its immersed weight. When the Reynolds number is less than about 10^3 the drag force may be expressed:

$$D = \alpha \mu v l = \frac{\alpha R \mu^2}{\rho}$$

where α is a function only of R, the Reynolds number. From the experiments it is possible to construct a curve of $\alpha R : R$. Knowing the immersed weight of the modified prototype ($= D$) and the viscosity and density of the fluid αR_p can be calculated. Reference to the experimental curve produces R_p whence:

$$v_p = \frac{\mu_p R_p}{\rho_p l_p}$$

The only apparatus required is a series of U-tube viscometers and a hydrometer and a wide dropping tank deep enough for the model to travel at terminal velocity for a time sufficient such that it can be measured with a stop watch. A suitable range of Reynolds numbers can be obtained by mixing liquids of different viscosity such as glycerol and water. Thixotropic liquids (for example, methyl cellulose and water) must not be used.

Models are widely used to investigate the hydrodynamics of prototypes larger than themselves, but their use with very small prototypes is relatively unexplored.

Continuous Recording of the Hydrostatic Pressure in a Sea Anemone

Investigation of the hydrostatic skeleton in the invertebrates has generally been limited to the use of manometric techniques to determine the hydrostatic pressures involved both at rest and during activity[1]. Some workers, notably Batham and Pantin[2], have based their results on manometer readings taken at frequent intervals, but there seem to be few reports of work using continuous recording of pressure changes.

Some recordings have been made of the hydrostatic pressure of the coelenteron of the actinian polyp *Tealia felina* with the view of making some comparison with the results previously obtained on *Calliactis* and *Metridium*[1,2] before investigating other animals. A four-channel pen recorder (manufactured by E. and M. Instrument Co., Texas) was coupled by d.c. amplifiers to a myograph to record activity, and a Bourdon gauge, by way of a photoelectric transducer, to record, simultaneously, pressure. The Bourdon gauge used had the advantage of low fluid displacement, about 15 mm³ per 130 cm water pressure applied, and a sensitivity of 1 cm pen deflexion for 6 cm water pressure at maximum gain. It was not convenient, however, to work at maximum amplification for long periods, but the instrument proved stable enough at lower gain to register constant pressures steadily over periods of at least several hours.

A glass cannula of 3 mm diameter with the mouth cut obliquely to minimize blockage was inserted through the lower part of the wall of the column of an anemone and connected to the gauge. A thread from the margin of the disk and a light isotonic lever were used to record simultaneously the movement of the *Tealia*. While the anemone remained fairly constant in shape the pressure recorded from the enteron gave values of up to 3·5 cm of water, comparable with those observed by Chapman for *Calliactis*[3]. Some considerable movement was recorded at night, including what appeared to be sharp retractions, but with no corresponding changes in pressure. A gradual increase in pressure of 2·8 cm of water was recorded, however, during 20 min at the commencement of activity and this was sustained during activity. This is in general agreement with the findings of Batham and Pantin[2], who point out that an increase in muscle activity will raise the average hydrostatic pressure. A typical recording of a naturally occurring contraction (Fig. 1*a*) shows a rapid build-up in pressure and a slow subsequent drop. The maximum pressure recorded from a natural contraction was 10 cm of water, the anemone in this case taking 1·75 h before returning to the initial pressure. Mechanical stimulation by poking hard at the base of the column gave maximum pressures (15 cm of water) when the anenome was half retracted before stimulation (Fig. 1*b*), but pressures of only 2 or 3 cm of water when the polyp was originally fully expanded. Long periods of relaxation were again experienced. These values of pressure recordings are again comparable with those observed in *Calliactis*[3] by use of manometric techniques. Although the Bourdon gauge in its present form is not so sensitive as the more refined manometric techniques[2], its use over longer periods and for continuous pressure readings without observational fatigue is clearly of value. Investigations are proceeding into the continuous recording of the coelomic pressure during burrowing in annelids and of the pressure relationships of heart and haemocoele in molluscs.

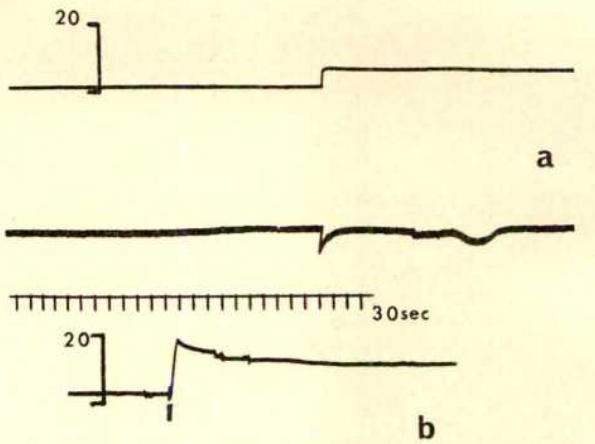

Fig. 1. Recordings of hydrostatic pressure changes in *Tealia*. Upward movement of the pressure traces indicates an increase in pressure, the scales representing a pressure of 20 cm of water and a 30-sec time mark. *a*, The sharp increase and slow relaxation of pressure (upper trace) of a naturally occurring contraction (lower trace, downward deflexion); *b*, rapid retraction of the anemone with mechanical stimulation at the point indicated

MICROBIOLOGY

Effects of the Diethyl Ester of Pyrocarbonic Acid on Bacteriophage and Transforming DNA

The synthesis of the diethyl-ester of pyrocarbonic acid (DEP) was first reported by Boehm and Metha[1] in 1938. Later, G. Hecht[2] observed that this compound had a strong bactericidal effect. It is also known that DEP rapidly decomposes in water into toxicologically indifferent products; carbon dioxide and alcohol:

$$C_2H_5—O—CO—O—CO—O—C_2H_5 + H_2O \rightarrow 2\,C_2H_5OH + 2\,CO_2$$

These two characteristics—its bactericidal effect and its decomposition in water—make it useful as a sterilizing agent. In recent years a number of publications recommended it as an advantageous preservative for use in the food industry[3]. The mechanism of its bactericidal effect is not yet known exactly.

We performed experiments aimed at testing the effect of DEP on bacteriophage and on DNA capable of genetical transformation.

The phage material and the bacterial strains used in our experiments originated from the collection of the Microbiological Institute of the Medical University of Szeged (Hungary) and the DEP was a commercial product of Farbenfabriken Bayer *A.G.*

The virulent *Bacillus subtilis* phage referred to as 4*L* was propagated in yeast extract peptone media[4] on the sensitive strain of *Bacillus subtilis*, Marburg. The lysate we received contained 5×10^7 plaque-forming units (p.f.u.) per ml. 1 ml. of the lysate was incubated at room temperature with 0·02 ml. DEP (dissolved in 96 per cent ethanol in concentrations of 50–0·5 per cent) and after 24 h (after the decomposition of DEP) the number of infective phage particles was tested as described by

Table 1. INHIBITORY ACTION OF DEP ON 4L PHAGE

Initial P.F.U. per ml.	Concentration of DEP at the beginning of incubation (mg DEP per ml.)	P.F.U. per ml. after 24 h incubation	Inhibition (per cent)
5×10^7	0	5×10^7	0
5×10^7	0·1	5×10^7	0
5×10^7	1·0	5×10^6	90
5×10^7	10·0	0	100

Ivanovics and Csiszár[4]. The results of the experiment are shown in Table 1.

In another experiment we studied the effect of DEP on DNA capable of genetical transformation. The DNA was prepared from *Bacillus subtilis* 168 prototrophic strain according to the method of Marmur[5]. 1 ml. of DNA (0·8 mg DNA per ml., dissolved in 0·015 M sodium chloride plus 0·0015 M trisodium citrate, *p*H 7·0) was incubated at 0° C with 0·02 ml. DEP (alcoholic solution in concentrations of 50–0·5 per cent) and after 4 days the transforming activity of 0·1 ml. DNA solution was tested on the tryptophan auxotrophic strains of *Bacillus subtilis* 168 according to the method of Anagnostopoulos and Spizizen[6]. Table 2 summarizes the results of these experiments.

Table 2. EFFECT OF DEP ON DNA CAPABLE OF GENETICAL TRANSFORMATION

Initial concentration of DEP in a 0·8 mg DNA per ml. solution (mg DEP per ml.)	Percentage transformation to prototrophy by 0·1 ml. DNA after incubation for 4 days
0	0·10
0·1	0·18
1·0	0·10
10·0	0·12

These data show that DEP possesses a phage-inhibiting action in addition to its well-known bactericidal effect. On the other hand, the fact that the transforming activity of DNA practically was not altered by DEP indicates that its phage-inhibiting action probably takes place through the protein part of the phage particle.

At present, in our other experiments we routinely use DEP for phage elimination in bacterial filtrates and for sterilizing different DNA solutions.

CYTOLOGY

Electron Micrography of Human Chromosomes

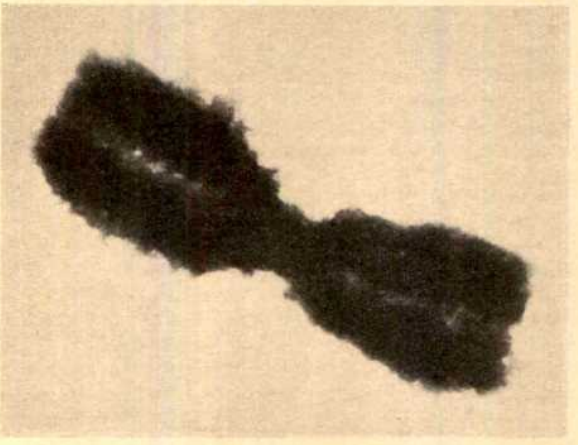
As a field of research, human cytogenetics is only 9 years old, but outstanding results have already been reported in numerous diseases. Further advances depend now essentially on the resolution of the microscope; as the limits of the optical system seem to have been reached, important new developments in cytogenetics should not be expected.

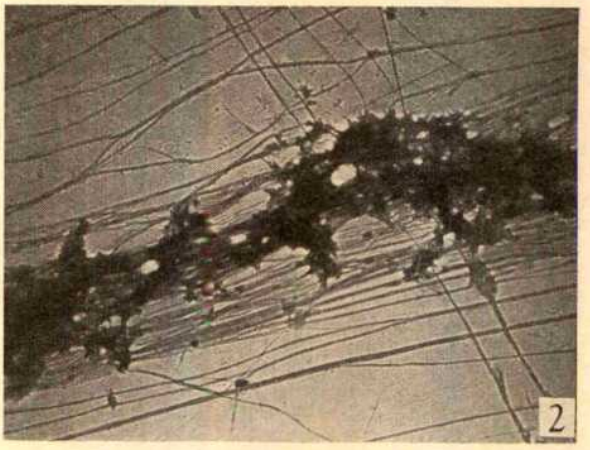
We therefore approached the present problem by electron microscopy, as several authors have recently done for animal cells of different origins[1–4].

Mitoses were obtained from human blood cultures and submitted to hypotonic solutions containing trypsin and RNase. Either of the following techniques was then used:

(1) The cell sediment was fixed in acetic acid–methanol and spread on collodion films. The best mitoses were selected by phase-contrast microscopy and their supporting film transferred on grids which were floated on uranyl acetate solution. Fig. 1 shows one chromosome from such a mitose. After DNase treatment, chromosomes appear empty, with an electron-dense envelope.

(2) The cell suspension was digested with trypsin–RNase–EDTA, mixed with a cytochrome solution, and spread on the surface of a Langmuir trough. The material was picked up on formvar–carbon-coated grids, fixed, dehydrated and conically shadowed with platinum. Depending on the strength and duration of enzyme action, chromosomes and nuclei appeared more or less fragmented, giving rise to many fibres of different sizes, most of which were parallel and showed some periodicity (Figs. 2–4). Fairly frequently, loose bundles of individual





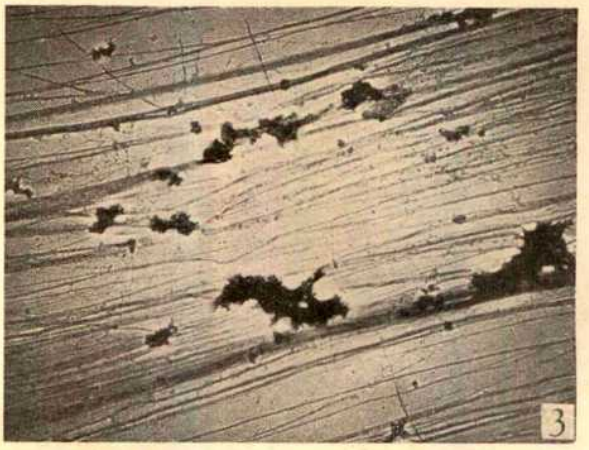


Fig. 1. A chromosome No. 1 (Denver classification) (× 18,000)

Figs. 2 and 3. Bundles of packed DNA fibres which can be followed over a length of at least 30μ (× 8,000)

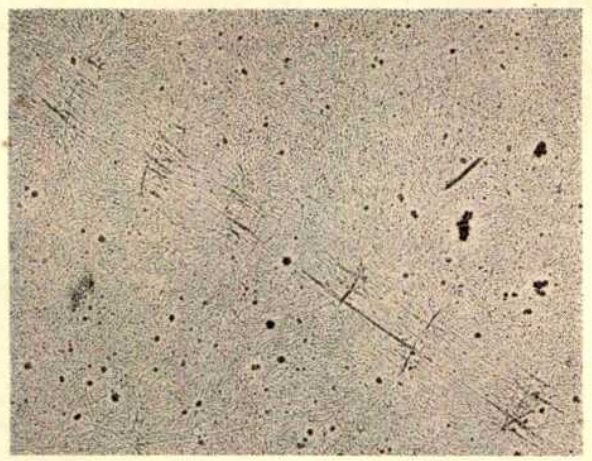

Fig. 4. Loose bundles of individual DNA threads which can be followed over a length of at least 40μ. They present cross-links at rather regular intervals. From these points, loops of individual DNA fibres spread on. No free ends of threads can be seen (× 24,000)

DNA threads presenting cross-links at somewhat regular intervals were found.

These methods enable investigation of human chromosomes to be made at much higher magnifications than previously; they show DNA fibres and their gross arrangement and structure.

Cytoplasmic Inclusions in Neurones of Cercopithecus Monkeys

During the examination of spinal dorsal root ganglia from a large number of South African vervet monkeys (*Cercopithecus aethiops pygerythrus*) we have observed that eosinophilic cytoplasmic bodies are usually present in a high proportion of ganglion neurones at all levels of the cord. These bodies may be single or multiple, are commonly round but may appear discoid when seen on edge (Fig. 1) and may have basophilic internal structures (Fig. 2). Inoculation of ganglion suspensions into monkey kidney tissue cultures has not produced changes in these cultures.

Similar bodies have only very occasionally been observed in the anterior horn cells of the spinal cord. Cytoplasmic inclusions had not been noted elsewhere in the central nervous system until they were seen in the thalami of several monkeys used in the transmission of a non-viral toxicosis from ticks fed on these animals. A careful search of sections of the brains and cords of vervet monkeys used in a variety of other experiments has revealed identical inclusions, chiefly in the thalami, in over half the animals examined, including monkeys not inoculated in the central nervous system. In the brain the bodies are

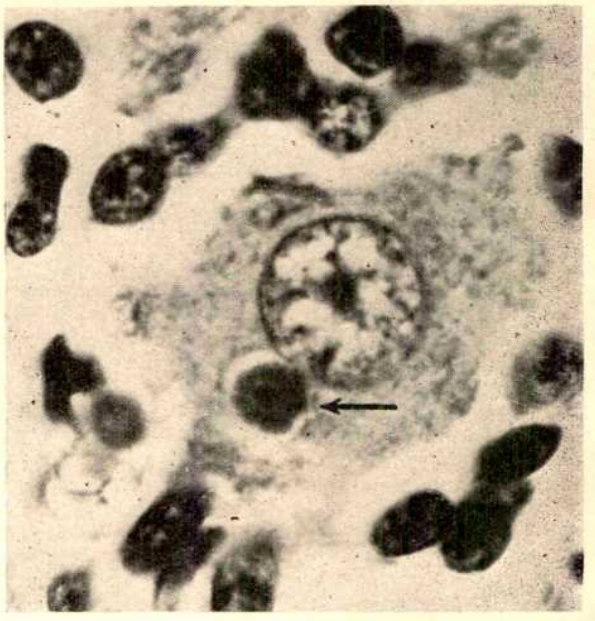

Fig. 2. Inclusion body in spinal ganglion neurone. Lendrum's stain (× *c.* 1,450)

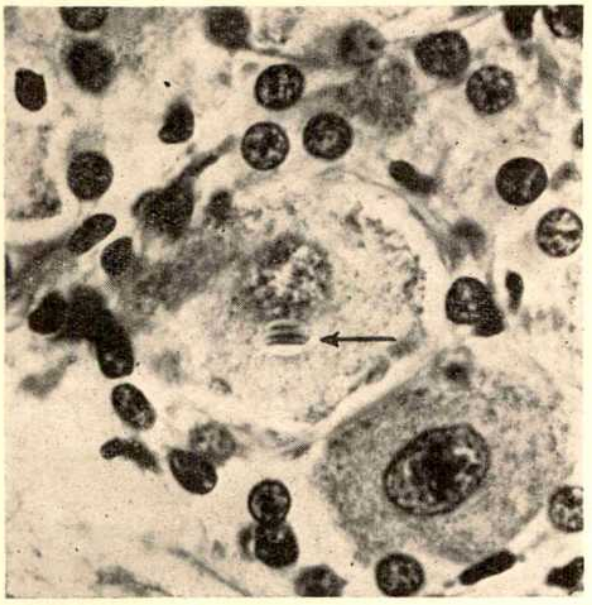

Fig. 1. Inclusion body in spinal ganglion neurone. Shorr's stain (× *c.* 900)

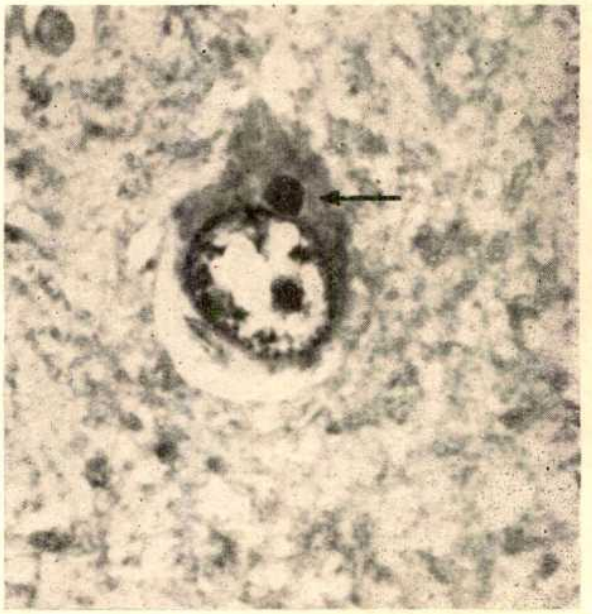

Fig. 3. Inclusion body in thalamus neurone. Haematoxylin and eosin stain (× *c.* 1,450)

usually round and regular in outline, measuring 4–5μ in diameter (Fig. 3). They are eosinophilic, but may have faintly discernible unstained internal structures. The bodies usually occur singly within neurones; but a large number of cells, especially in groups, may be affected, and in one section of thalamus measuring 8 mm by 10 mm more than ninety inclusions were seen. No clinical signs are associated with their presence.

These bodies were also observed in the thalami of monkeys inoculated intracerebrally with human brain biopsy material from cases of subacute inclusion encephalitis, and wrong conclusions about their presence may have been drawn if they had not been noted in the brains of other monkeys.

VIROLOGY

Susceptibility of the Rhesus Monkey (*Macaca mulatta*) to *H*-1 Virus

THE host range of the *H*-viruses, a new group of small agents approximately 200 Å in diameter, is as yet unknown. *H*-1, *H*-3 and *HB* have been isolated from tumours, embryos, and placentae of human beings[1,2], while *RV* and *X*-14 have been obtained from tumour tissue of rats[3,4]. All these viruses are distinguished by their ability to produce an infection in new-born hamsters that results in death or a 'mongoloid-type' deformity, depending on the concentration of virus given. The present communication indicates that the rhesus monkey (*Macaca mulatta*) is also susceptible to an *H*-virus.

Two adult and healthy female monkeys, approximately 3 years old, were injected subcutaneously with 0·5 ml. of *H*-1 virus that had a haemagglutination (HA) titre of 1 : 2,560 with guinea-pig red cells. This was the same virus suspension previously described and used[5] for one of two human cancer patients (No. 2) who developed an *H*-1 virus viraemia and afterwards high antibody titres to *H*-1 after injection of this agent. The two monkeys injected with *H*-1 also developed a viraemia. Whole blood, drawn from the animals 4 days after the injection of virus, was inoculated subcutaneously into 2 litters each of new-born hamsters[6], all of which died within 13 days. *H*-1 virus was isolated from the livers and kidneys of the dead hamsters. The pre-injection blood, used as a control, caused no harm to two other new-born hamster litters. Sera from the latter animals, bled at 21 days of age, were tested for the presence of antibodies to *H*-1 and were negative.

Both pre-injection and post-injection sera from the monkeys were examined for the presence of antibodies to *H*-1. After treatment with kaolin to remove non-specific inhibitors[7,8], the sera were tested in various dilutions for their ability to inhibit the haemagglutination of guinea-pig red cells by 8 units of *H*-1 virus. The results were expressed as the highest serum dilution that completely inhibited the haemagglutination. HA-I antibodies appeared by the twelfth day in one monkey and were present in both animals by the nineteenth day (Table 1, Monkeys No. 1 and No. 2). The antibodies had disappeared by day 33, at which time the monkeys received a second injection of the same virus preparation. An anamnestic-type response occurred. The antibodies were specific for *H*-1 since similar tests with *HB*, *H*-3 and *RV* viruses were negative. Sera with HA-I titres also neutralized *H*-1. When undiluted and 10^{-1} dilutions of these sera were mixed with an equal volume of the *H*-1 virus used for injection of the monkeys, they afforded new-born hamsters complete protection, while a mixture of pre-injection sera plus virus killed control hamsters in 5 days. It should be noted that the monkeys did not appear ill at any time.

Table 1. HAEMAGGLUTINATION-INHIBITION TITRES TO *H*-1 VIRUS OF SERA FROM ADULT RHESUS MONKEYS PREVIOUSLY INJECTED WITH *H*-1

* Guinea-pig cells were used for these procedures. Results are expressed as the highest serum dilution that completely inhibited haemagglutination of the cells by 8 units of *H*-1 virus.

The HA-I titres produced in the two normal monkeys were rather low compared with the high HA-I titres of 1 : 2,560 or more, previously observed in the human cancer patients. Since *H*-1 has been isolated from proliferating tissues such as human tumours, embryos, and placentae, it was thought that this agent might possibly multiply best where rapidly growing tissues were present. Accordingly an attempt was made to find a rhesus monkey with a spontaneous tumour. None was obtained, but through the courtesy of Dr. S. Munroe, a 1-year-old male rhesus monkey carrying three induced Rous-virus tumours[9] was made available. This animal received 0·5 ml. of the same suspension of *H*-1 given to adult monkeys No. 1 and No. 2. It developed an HA-I antibody titre of 1 : 1,280 to *H*-1 by day 19 (Table 1) at which time it died of complications due to the induced Rous-virus tumours. It is certainly not possible to ascribe the high antibody titre observed in this single animal to the presence of rapidly growing tissues. On the other hand, it is noteworthy that no impairment of antibody production to *H*-1 was observed in this monkey because tumours were present and the animal was in a terminal state.

In addition to the adult monkeys, six new-born full-term rhesus babies, housed at the Bionetics Research Laboratory, Falls Church, Virginia, were injected subcutaneously on the day of birth with 0·5 ml. of *H*-1 virus (Table 2). Three different strains of *H*-1 virus with high HA titres of 1 : 5,120 were used for these six animals. Monkeys No. 536 and No. 538 were injected subcutaneously with 0·5 ml. of the first hamster passage of *H*-1 isolated from the blood of human patient No. 2 noted previously, 4 days after the injection of virus. Monkeys No. 577 and No. 578 received another first hamster passage from this same 4-day blood, while monkeys No. 565 and No. 566 were injected with virus derived from the third hamster passage of *H*-1 isolated from a human embryo. Five of the six animals developed HA-I and neutralizing antibodies to *H*-1. The sixth animal (No. 538) died at 2 weeks, possibly before antibodies could be detected. No antibodies to *HB*, *H*-3 or *RV* were found in any of the sera. All the monkeys died with an autopsy diagnosis of pneumonia. The attendant nursery-room staff recorded as noteworthy that all six monkeys had a 'rough coat' and that 'painful' skin rashes occurred in four of the animals (Nos. 536, 566, 577 and 578). These observations were considered unusual in a large nursery with a daily capacity at any one time of approximately 45 individually isolated rhesus babies. The average expected death rate for such full-term infants is about 25 per cent.

Table 2. HAEMAGGLUTINATION-INHIBITION TITRES TO *H*-1 VIRUS OF SERA FROM RHESUS MONKEYS INJECTED AT BIRTH WITH *H*-1*

Time of treatment†	Monkey No. 536 (♀)	538 (♀)	577 (♂)	578 (♀)	565 (♂)	566 (♀)
Pre-inj.	0	0	0	0	0	0
2 weeks	320	0 Died	320	320	40 Died	0
3 weeks	—		1,280	1,280 Died		80 Died
2 months	160 Died		2,560			
3 months			320 Died			

* Same procedures used for titration as outlined, Table 1.
† Three different strains of *H*-1 virus were used for injections, two monkeys were injected with each strain.

On the basis of this preliminary work, death of the baby monkeys cannot be attributed to the virus injection. It can be concluded, however, that both adult and new-born rhesus monkeys are susceptible to infection with *H*-1 virus. A related observation is the recent report[10] that *H*-1 and *H*-3 viruses can be grown and passaged in monkey as well as human tissue cultures with the production of a cytopathic effect (CPE).

The work on new-born monkeys was carried out in collaboration with the staff of the Bionetics Research Laboratory, Inc., Falls Church, Virginia, under a contract to the National Cancer Institute, Bethesda, Maryland. I thank Dr. A. Pallotta, Dr. R. Miller and the nursery room staff for their help, and I also thank Dr. S. Munroe for supplying the juvenile monkey with Rous-virus-induced tumours.

This work was supported by grants *CA*–02042–11, *CA*–07826–01 and *CA*–07826–02 from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service, and grants *E*–110*E* and *E*–343 from the American Cancer Society.

VETERINARY SCIENCE

Hypocuprosis of Cattle in the Argentine

Hypocuprosis in cattle is defined by low concentrations of copper in the liver[1–3] or in the blood[2,4,5] or other tissues[6] and is usually associated with some general external symptoms such as unthriftiness, diarrhoea and depigmentation of the hair[4]. Anaemia is sometimes, but not always, present. The levels of copper in the tissues which have come to be regarded as diagnostic of hypocuprosis are for the blood less than 0·70 γ per ml.[4,6] and for the liver less than about 30 (refs. 1 and 6) p.p.m. dry-weight; the severity of the condition increases as the tissue concentrations of copper fall below these thresholds, until at levels of 6 p.p.m. dry-weight of copper in the liver, sudden death in cattle has been recorded[2].

Hypocuprosis has been reported from a number of areas of the world[7,8]. Of these reports, only a few have been concerned with a deficiency induced by the presence of unusually low concentrations of copper (less than 3 p.p.m.) in the feed[4]. The majority of the reports[7] refer to a 'conditioned' copper deficiency in which there is a blocking of the utilization of normal amounts of copper in the forage (6–16 p.p.m.) by other constituents present, such as molybdenum and sulphate. These two components of the forage have been amply demonstrated to limit the copper storage in sheep[9], and have been reported to be involved in the same phenomenon in cattle[10].

Up to the present no information has been available regarding the copper status of cattle in the Argentine. Now, however, as part of a project initiated by the Special Fund of the United Nations with the assistance of the Food and Agriculture Organization, and the co-operation of the Instituto Nacional de Tecnologia Agropecuaria, this work has been undertaken. The report presented here indicates, for the first time, that conditions exist in parts of the Province of Buenos Aires which induce low levels of copper in the liver and blood of cattle pastured there. The values given in Table 1 refer to Aberdeen Angus cattle of the breeding herds during the period of active growth and located mainly in the eastern half of the Province.

From time to time reports had been received from different areas of the Province that some of the animals in the herds were unthrifty, were affected with diarrhoea and had rough coats, the hair of which showed depigmentation. On investigation these conditions were confirmed; however, the depigmentation was found to range from a mild browning about the ears in some animals to a more general-

† On dry-weight basis.

ized lightening of the colour of the hair along the back and the flanks in others, to a frank greying of the entire coat in still others.

The pastures which the animals were grazing in these areas were mixtures of grasses, trefoils and herbs. Samples of these pastures were collected by random plucking across the sward, bulked and analysed for copper, molybdenum[11] and inorganic sulphate[12]. The values found for the copper contents showed that these were within the normal range, being from 6 to 11 p.p.m. dry-weight. The molybdenum concentrations were, however, as high as 27 p.p.m. dry-weight and not lower than 3 p.p.m. dry-weight. The sulphate contents ranged from 0·27 to 0·63 per cent dry-weight.

The possibility of the existence of a conditioned copper deficiency in the animals grazing these pastures and showing these symptoms was therefore explored. Samples of blood were taken by venepuncture with a stainless steel needle and, at the same time, samples of liver tissue were secured by biopsy[6]. The samples were then analysed for their copper content after the organic matter present had been destroyed by wet digestion with mixed sulphuric, perchloric and nitric acids[13].

Comparative data of the blood and liver copper concentrations from cattle in four zones investigated, together with some information on the copper, molybdenum and sulphate content of the pastures in the same areas, are presented in Table 1. Data from Zone 1 are divided into three parts. On the affected area (*a*) where the animals showed rough and visibly depigmented coat, diarrhoea and retarded growth, blood and liver samples were taken three times at approximately three-week intervals. On each occasion the same low values were found indicating a condition of chronic hypocuprosis. On another area (*b*) where the animals were obviously in better condition, showing little sign of depigmented hair and no diarrhoea, the copper-levels of the blood and liver were significantly higher than those encountered on the affected area (*a*). A sub-group of animals of the same strain as those grazing area (*a*) of Zone 1 were transferred following weaning to improved pasture on the high land of the Balcarce Experiment Station. These animals, which presented prime appearance with normal lustrous coats and no diarrhoea, were sampled at the same time as those on Zone 1 (*a*). The animals on Zone 3 showed extreme depigmentation of the hair.

While more extensive information will be necessary before a causal relationship can be drawn between the hypocuprosis of these cattle and the copper, molybdenum and sulphate contents of the forage which they graze, the data presented strongly suggest that these factors may be involved.

Where the copper : molybdenum ratio is less than 2·8 : 1 the incidence of a hypocuprosis in the animals is evident; where the ratio is greater than 2·8 : 1 the copper-levels of the liver and blood of the animals are significantly higher. The effect of copper supplementation on the copper status of animals in the affected areas is now under investigation.

The description of the soils where this hypocuprosis occurs will be reported elsewhere; but in general they are alkaline rather than saline—a condition which would lead to greater availability of molybdenum to plants. The waters lying on these soils as well as those of subterranean origin have been found to contain up to 1,000 p.p.m. of sulphate. This high sulphate intake in the water, superimposed on that found in the pastures, could raise the total sulphate intake to a level where relatively small amounts of molybdenum might be potentiated[9] to reduce the copper reserves of cattle exposed to this environment. An investigation is being carried out of the efficacy of treatment with copper (as Cu-EDTA given subcutaneously) in preventing this hypocuprosis.

We thank Dr. J. P. Culot for some of the molybdenum analyses of the pastures and for comments regarding the soil conditions in the area, and Dr. G. K. Davis for valuable discussions.

AGRICULTURE

Blood Copper-levels in Sheep in Relation to Genetic Factors, Parity and Previous Swayback History

Blood copper-levels are known to be associated with the incidence of swayback in lambs (see Barlow *et al.*)[1]. A sample of fifty-five ewes was bled some 6 weeks prior to lambing and almost a year after a 15 per cent incidence of swayback had occurred among the lambs in the flock from which these ewes were drawn. The flock consists of three breeds (Scottish Blackface, South Country Cheviot and Welsh Mountain) and the crosses between these breeds. The ewes belong to two breeding classes, outbred (F_2) and 25 per cent inbred (I_1), and to four parities. The choice of animals for bleeding took account of these subdivisions within this flock and of swayback history of the lambs born to ewes of parity 2 and more in 1964. Blood copper values were estimated by the method of Butler and Newman[2].

The blood copper values (obtained by least squares) for the effects of breed and differences due to inbreeding, parity (in-lamb for first time versus later parities), swayback history and cross-breeding, are shown in Table 1. Breed had an apparent effect on total variation in blood copper ($0{\cdot}1 > P > 0{\cdot}05$), although not all the six breed types differed significantly from each other. On average, Blackfaces had the lowest blood copper value. Heterosis was suggested by the crosses having on average higher

Table 1. Blood Copper Values (μg/100 ml. Whole Blood) for Six Breed Types of Ewe and Differences due to Cross-breeding, Inbreeding, Parity and Swayback History

Class	Copper value*	*S.E.*
Blackface	27·79	4·80
Cheviot	35 35	4·78
Welsh	40·50	4·70
Cheviot–Welsh	43·15	4·83
Blackface–Welsh	37·89	4·67
Blackface–Cheviot	40·75	4·67
Cross-bred mean–purebred mean†	6·05	3 35
I_1–F_2	−3·63	3·32
Deviation, from later parity ewes with no previous swayback lambs, of		
First parity ewes	−10·08	4·26
Later parity ewes with previous swayback lambs	−15·68	3·98

* The breed effects shown refer to the F_2 class and to the later parity with no previous swayback lambs. The average of the six fitted breed values (37·57) may be compared with the actual average of 28·55 for the blood copper values determined for the 55 ewes.

† Difference derived from the fitted breed values.

values than the average of the purebreds ($0{\cdot}1 > P > 0{\cdot}05$). The difference between inbreds and outbreds was not significant. Most clearly, ewes which nearly a year ago produced lambs with swayback had much lower blood copper values than contemporaries which had previously had normal lambs ($P < 0{\cdot}001$). Females in-lamb for the first time had significantly lower values than ewes which had lambed previously ($P < 0{\cdot}05$).

For about 6 weeks prior to bleeding, the ewes, which ran together as one grassland flock, had access to a mineral lick containing 718 p.p.m. copper. It is possible, therefore, that sheep may have ingested different quantities of mineral, which could complicate interpretation of the results. However, the special management circumstances of the experimental flock are such that there was no segregation of the flock by breed or by the other subdivisions in the analysis. In spite of the access to a mineral lick containing copper, only two of the fifty-five sheep had blood copper values greater than the 60 μg/100 ml. whole blood, which has been accepted as a 'normal' level in the literature (for references see Barlow *et al.*[1]).

It has recently been found[3] in the same flock that the incidence of swayback in lambs in 1964 was clearly associated with breed and breed cross. The mean blood copper values of the three pure breeds ranked inversely to the percentage of lambs with swayback among these breeds in the previous year. The overall correlation between the present blood copper levels of the six breed types of ewe and the percentile incidence of swayback among the lambs of the same six breed types in the same flock a year ago was $-0{\cdot}82$ ($P < 0{\cdot}05$). The genetic implications of these findings merit further investigation in relation to the swayback syndrome.

PSYCHOLOGY

Age, Cardiac Output and Choice Reaction Time

In an earlier communication to *Nature*[1] it was argued that the attempt to resolve the discrepancy in data on choice reaction time in relation to age in terms of the effective duration of signals[2] must be regarded as inadequate. The observations were based on a small sample ($N = 48$) of data from a psycho-physiological study of the possible effects of ageing on professional (that is, airline, military and test) pilots. The present communication is a brief account of some of the further results obtained to date in a larger sample ($N = 201$).

The design of the psychological experiments is intended to reflect the fact that flying requires, *inter alia*, making high-speed decisions and detecting low probability signals, as well as an ability to receive and retain significant amounts of information in the course of routine control procedures. Consequently in the measurement of choice reaction times, latencies of responses are recorded not only under normal ('basic') conditions but also under those of 'information overload'—in an attempt to estimate 'reserve capacity'. For a more detailed description of the methods used in this investigation the reader is referred to the earlier reports[1,3,4]. The evidence summarized in Table 1 makes it clear that, as before, the principal age differences in our sample of some two hundred active pilots are to be found in the intercept constant of the formula for choice reaction ($RT = a + b \log_2 n$) under conditions of information overload, not in the slope constant. The b constant, however, appears to be directly related to cardiac output, as assessed on the basis of ballistocardiogram stroke volume and of heart rate, recorded after exercise. Furthermore, the results of the pulmonary physiology studies under conditions of maximum effort are also in line with this trend.

Table 1

(Response time $= a + b \log_2 n$)

Correlation r^* = rate of gain of information with age and cardiac output (ballistocardiogram stroke volume and heart rate)

	Serial choice task alone		Serial choice task with overload		Difference (basic-overload)	
	r	p	r	p	r	p
Rate of gain of information						
× Age	−0 13	NS†	−0 27	0 001	0 25	0·001
× Cardiac output (pre-exercise)	0 06	NS	0 01	NS	−0·06	NS
× Cardiac output (post-exercise)	0 05	NS	0 08	NS	0 04	NS
Constant a (intercept)						
× Age	0·03	NS	0 22	0·01	0·18	0·02
× Cardiac output (pre-exercise)	−0 04	NS	0 01	NS	0·03	NS
× Cardiac output (post-exercise)	0·02	NS	−0·02	NS	−0·03	NS
Constant b (slope)						
× Age	0 02	NS	0 07	NS	0·07	NS
× Cardiac output (pre-exercise)	0 01	NS	−0·05	NS	−0 05	NS
× Cardiac output (post-exercise)	−0·08	NS	−0·26	0·01	0·23	0·01

		r	p
Cardiac output	(Pre-exercise) × age	0 15	NS
	(Post-exercise) × age	−0·17	0 05
Oxygen pulse	(Maximum effort) × age	−0·12	NS
	× Difference in rates	−0 20	0 01

* Quantitative analysis carried out with the aid of a Burroughs 5500 computer
† NS: not significant.

It is felt that these findings raise important questions of fact and of analysis. In the first place, they confirm the general impression that age differences in physiological and psychological tests are more revealing when observed under conditions of stress than under baseline or resting conditions[5]. In the second place, they add to the slowly accumulating evidence[1,4,6–8] that the population samples in those studies of ageing in which the occupational and health status of the subjects was not clearly defined may have to be regarded in some sense as non-normal. In particular, with reference to data on choice reaction times, the present investigation suggests that those earlier investigations which reported slowing of response with age as an increase in the slope constant must have included, no doubt inadvertently, sub-clinical cases of cardiovascular disorder. Of course, studies of ageing which would be entirely free of pathology are to some extent imaginary; however, the difficulties which arise about 'unscrambling' the effects of ageing and those of minimal pathology are not the most convincing confirmation of the supposed vulnerability of function in later adulthood.

This work is supported by a grant from the U.S. National Institutes of Health (*HD*-0518).

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, February 21

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Lt.-Col. J. A. Simson, M.C., and Mr. C. J. Sweeney, O.B.E.: "The Ordnance Survey and Land Registration".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Conference on "Delay Devices for Pulse Compression Radar".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. J. C. Wood: "Developments in the Control of Ectoparasites of Livestock".

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. Bourlière (University of Paris): "The Ecology of Herbivores in the African Savanna and Forest" (Further lecture on February 23).*

Tuesday, February 22

INSTITUTION OF CHEMICAL ENGINEERS, SOUTH-EASTERN BRANCH (at the Royal Aeronautical Society, Hamilton Place, London, W.1), at 2 p.m.—Symposium on "Some Practical Aspects of Process Control by Computer".

SOCIETY FOR ANALYTICAL CHEMISTRY, SPECIAL TECHNIQUES GROUP (in the Lecture Theatre, Wellcome Building, Euston Road, London, N.W.1), at 3 p.m.—Meeting on "Special Techniques in Gas Analysis".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.E./I.E.R.E. MEDICAL ELECTRONICS GROUP (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. P. A. Marton: "Muscular Control".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. G. E. H. Reuter: "Some Mathematical Problems in the Theory of Random Processes" (Inaugural Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. F. Gale: "Microbes, Macromolecules and Mayhem". (Twelfth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation).*

UNIVERSITY OF LONDON (in the Engineering Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Jean Hiernaux (Brussels): "Biological Studies on Some Human Populations of Central Africa. I. The Populations of Ruanda. Methods of Analysis".*

Wednesday, February 23

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the Food and Microbiology Groups, at the School of Pharmacy, Brunswick Square, London, W.C.1), at 2.30 p.m.—Meeting on "Microbiological Flora in Relation to Quality".

GEOLOGICAL SOCIETY (at the Royal Institution, Albemarle Street, London, W.1), at 5 p.m.—Prof. V. Beloussov (Academy of Sciences of the U.S.S.R.): "The Earth's Crust and the Upper Mantle"; Dr. M. H. Hey, Mr. E. A. Jobbins and Dr. A. J. Meadows: "The Barwell (Leicestershire) Meteorite, 24 December 1965" (demonstration).

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (in the Physics Department, Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Dr. J. W. S. Cassels, F.R.S.: "What are p-Adic Numbers?"*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. L. Bliss: "Remote Synchronization of Television Waveform Generators".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. F. Bentham: "Theatre Lighting in Britain To-day".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E./I.E.E. MEDICAL ELECTRONICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Discussion on "Mental Stresses Induced by Audio and Visual Hazards" opened by Mr. B. Shackel.

SOCIETY OF ENVIRONMENTAL ENGINEERS, PACKAGING GROUP (in the Mechanical Engineering Department, Imperial College, London, S.W.7), at 6 p.m.—Mr. F. Bailey: "Climatic Protection of Packaged Goods?".

SOCIETY FOR ANALYTICAL CHEMISTRY, BIOLOGICAL METHODS GROUP (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Dr. Betty Hobbs: "Modern Techniques in the Bacteriological Examination of Food".

Thursday, February 24

PARLIAMENTARY AND SCIENTIFIC COMMITTEE (in the River Room, Savoy Hotel, London, W.C.2), at 11.30 a.m.—Annual General Meeting.

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. Henry Harris: "Hybrid Cells from Mouse and Man—a Study in Genetic Regulation".

ST. MARY'S HOSPITAL MEDICAL SCHOOL (in the Lecture Theatre of the Wright Fleming Institute, London, W.2), at 5 p.m.—Prof. R. A. Gregory, F.R.S.: "The Gastric Antral Hormone: Past, Present and Future" (Augustus Desiré Waller Memorial Lecture).*

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 5 p.m.—Prof. F. W. Spiers: "Biological and Physical Aspects of the Irradiation of Bone".*

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Prof. S. V. Perry: "Biochemistry of Muscle".*

INSTITUTION OF CIVIL ENGINEERS, HYDROLOGICAL GROUP (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Automatic Data Processing" introduced by Mr. C. W. Pugh.

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31-34 Gordon Square, London, W.C.1), at 5.30 p.m.—Prof. G. L. Huxley: "Excavations and Studies in Kythera 1965".*

UNIVERSITY OF LONDON (at the Institute of Psychiatry, The Maudsley Hospital, Denmark Hill, London, S.E.5), at 5.30 p.m.—Prof. D. Ploog (Munich): "Social Behaviour and Group Interaction in Squirrel Monkeys".*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. S. J. G. Semple: "Respiration and the Cerebrospinal Fluid." (Thirteenth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation).*

UNIVERSITY OF LONDON (in the Engineering Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Jean Hiernaux (Brussels): "Biological Studies on Some Human Populations of Central Africa. II. Ecological Factors: The Effects of Heredity and Environment".*

CHEMICAL SOCIETY (in the Large Physics Lecture Theatre, Imperial College, London, S.W.7), at 6 p.m.—Dr. E. J. Bowen, F.R.S.: "Light Emission from Organic Molecules" (Liversidge Lecture).

Friday, February 25

INSTITUTE OF RURAL LIFE AT HOME AND OVERSEAS (at Friends International Centre, Courtauld House, Byng Place, London, W.C.1), at 1.15 p.m.—Dr. Roy C. Heather: "Water in Rural and Urban Life".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. A. M. Dawson: "Fat Absorption".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. O. Scanlan and Mr. R. Levy: "Distributed Network Synthesis".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. D. J. Parkyn: "The Use of Test Line Signals for Remote Monitoring of Picture Quality at Unattended Transmitters".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. W. H. G. Armytage: "History of the Future".

Saturday, February 26

ASSOCIATION OF THE WILLIAM PENGELLY CAVE RESEARCH CENTRE (at the British Museum (Natural History), Cromwell Road, London, S.W.7), from 10.30 a.m. to 6 p.m.—Symposium on "Living in the Dark".

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Rex Wailes: "The Industrial Monuments Survey".*

Monday, February 28

INSTITUTE OF ACTUARIES (at Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Mr. S. Benjamin: "Putting Computers on to Actuarial Work".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. J. F. Böttchler (Leiden): "Pathology and Chemistry".*

UNIVERSITY OF LONDON (in the Eugenics Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. J. W. Tukey (Princeton University): "Numerical Spectrum Analysis". (Further lectures on March 2 and 4).*

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. I. Scollay and Mr. G. Caldwell: "Cold Press Moulding".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Mr. Michael Ward: "On the Highland Frontier of North Bhutan".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (with research experience in the field of algology, microbiology or biochemistry) IN THE DEPARTMENT OF MARINE BIOLOGY—The Registrar, University College of North Wales, Bangor, North Wales (February 25).

LECTURER IN THE SCHOOL OF EDUCATION—The Registrar, The University, Liverpool, quoting Ref. CV/418 (February 26).

LECTURER OR ASSISTANT LECTURER IN THE SUB-DEPARTMENT OF MATHEMATICAL STATISTICS—The Registrar, The University, Liverpool, quoting Ref. CV/427 (February 26).

UNIVERSITY LECTURERS (2) IN METALLURGY—The Secretary of Faculties, University Registry, Oxford (February 26).

LECTURER (honours graduate in science, pharmacy or medicine) IN PHARMACOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (February 28).

SENIOR RESEARCH ASSOCIATE (with a Ph.D. degree in chemistry or equivalent experience in research) to work on the chemistry of boron in collaboration with Prof. N. N. Greenwood—Prof. N. N. Greenwood, Department of Inorganic Chemistry, The University, Newcastle upon Tyne (February 28).

A.R.C. RESEARCH ASSISTANT (graduate in the biological sciences or in chemistry) IN THE DEPARTMENT OF BOTANY to work with Dr. J. S. Pate on the metabolic functioning of leaves—The Secretary, Botany Department, The Queen's University, Belfast, Northern Ireland (March 1).

LECTURER (with good honours degree and some postgraduate experience) IN MECHANICAL ENGINEERING—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (March 1).

SENIOR LECTURER OR LECTURER IN PHYSIOLOGY OR ZOOLOGY; and an ASSISTANT LECTURER OR DEMONSTRATOR IN ZOOLOGY—The Secretary, Wye College (University of London), near Ashford, Kent (March 1).

READER IN APPLIED MATHEMATICS at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 4).

READER IN NUMERICAL ANALYSIS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (March 4).

CHAIR OF ZOOLOGY—The Registrar, The University, Hull (March 5).

LECTURER/ASSISTANT LECTURER IN THE DEPARTMENT OF BIOCHEMISTRY—The Registrar, The University, Hull (March 5).

CHAIR OF MATHEMATICS—The Secretary, University of Stirling, P.O. Box 1, Stirling (March 7).

LECTURER IN THEORETICAL PHYSICS—The Registrar, The University, Newcastle upon Tyne, 2 (March 7).

LECTURER IN ZOOLOGY at University College, Dar-es-Salaam (University of East Africa)—The Inter-University Council, 33 Bedford Place, London, W.C.1 (March 8).

READER IN EXPERIMENTAL PHYSICS at Royal Holloway College, Englefield Green, Surrey—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 9).

SENIOR LECTURER or LECTURER IN MATHEMATICS at the University of Basutoland, Bechuanaland Protectorate and Swaziland—The Inter-University Council, 33 Bedford Place, London, W.C.1 (March 11).

RESEARCH ASSOCIATE (preferably young graduate with biological, surgical or pathological training, with or without previous research experience) for a two-year project on various experimental aspects of fibrosing mechanisms and wound healing in pigs, etc.—The Secretary, A.R.C. Institute of Animal Physiology, Babraham, Cambridge (March 15).

CHAIR OF HUMAN BIOLOGY—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (March 31).

CHAIR OF METALLURGY—The Registrar, The University, Sheffield (March 31).

THIRD CHAIR OF PHYSICS—The Registrar, The University, Sheffield (March 31).

UNIVERSITY LECTURER and a UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF ANIMAL PATHOLOGY in the School of Veterinary Medicine, for duties which will include teaching and research in either morbid anatomy or microbiology—T. D. Kellaway, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge (March 31).

UNIVERSITY LECTURER IN THE DEPARTMENT OF METALLURGY—The Secretary of the Appointments Committee of the Faculty of Physics and Chemistry, Chemical Laboratory, The University, Lensfield Road, Cambridge (March 31).

PROFESSOR (with registrable medical qualifications) IN THE DEPARTMENT OF ANATOMY, University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (April 12).

LECTURER or ASSISTANT LECTURER (with a good honours degree and experience in modern semiconductor circuit design, and preferably an interest in communications engineering) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Secretary, The University, Edinburgh (April 30).

CHIEF LIBRARIAN (scientist with an aptitude for, and experience in, library work, or trained librarian with an interest in science, particularly chemistry)—The Director, Paint Research Station, Waldegrave Road, Teddington, Middlesex.

HEAD (man or woman, with a good honours degree and teaching experience, and preferably previous service in a College of Education) OF THE GEOGRAPHY DEPARTMENT—The Clerk to the Trustees, Homerton College, Cambridge.

PHYSICAL CHEMIST capable of pursuing and supervising a range of basic and applied researches mainly on electrodeposition and electroforming—The Secretary, The British Non-Ferrous Metals Research Association, Euston Street, London, N.W.1.

PHYSICIST (with a good honours degree) to join a small group working on radiation protection problems associated with neutron radiation—The Director, Radiological Protection Service (Ministry of Health and Medical Research Council), Clifton Avenue, Belmont, Sutton, Surrey.

RESEARCH ASSISTANT IN THE DEPARTMENT OF FORENSIC MEDICINE to assist in a programme of research into the development of rapid methods of toxicological analysis—Dr. Harold V. Street, Department of Forensic Medicine, University of Edinburgh, Teviot Place Edinburgh.

RESEARCH DEMONSTRATORS (with a good degree in botany or horticulture) IN THE DEPARTMENT OF HORTICULTURE to assist with practical classes and carry out research in the physiology of horticultural plants—The Assistant Bursar (Personnel), University of Reading, Reading.

NEW grating SP200G infrared spectrophotometer

high resolution

Unicam now offers all the advantages of a grating filter monochromator combined with the proved features of the SP200 prism spectrophotometer. The first order of the NPL grating is isolated by four interference filters, brought into play by an automatic mechanism exclusive to Unicam. The resolution is as high as 3 cm^{-1} at 3000 cm^{-1} and stray light is less than 1% throughout most of the range and never exceeds 2%. The wavenumber accuracy is better than 2 cm^{-1} at 1000 cm^{-1} and 4 cm^{-1} at 3000 cm^{-1}. To this performance are added the advantages of the flat bed recorder, the accessible sample compartment and the convenient operation of the SP200. The new SP200G is constructed and finished to the high degree of precision for which Unicam instruments are famous. Descriptive literature is available on request.

Spectrum of ammonia gas recorded over 830 cm–1 to 955 cm–1 at the slowest scan speed under maximum resolution conditions using the scale expansion accessory.

CERN: AN OPPORTUNITY IN HIGH-ENERGY PHYSICS

AFTER the session of the Council of the European Organization for Nuclear Research (CERN) in December 1965, it was announced that twelve of the member States (that is, all of them with the exception of Greece) had decided to participate in the supplementary programme for the construction of a pair of intersecting storage rings to be operated in conjunction with the 28-GeV CERN proton synchrotron. This decision, the culmination of a long period of discussion, study and planning, has great significance in relation to the future development of the CERN Laboratory and of high-energy physics in Europe as a whole.

When, in the early 'fifties, a handful of enthusiastic and far-sighted senior physicists from a number of European countries came together to plan the CERN laboratory, few of them could have foreseen how successful their efforts would prove. In little more than 10 years a great centre of high-energy physics has been established with a world-wide reputation for carrying out research of high quality and originality. The movement of some of the brightest and most talented young scientists in this field from Europe to the United States has not been halted, but it has been supplemented by a similar, if smaller, movement in the opposite direction, so that it is beginning to take the form of a very desirable two-way stream. CERN has in fact become a centre of research attracting scientists from all over the world. As a centre of international scientific collaboration it has inspired, by its success, similar co-operation in other fields and serves as a model for the development of such centres.

The intersecting storage rings project envisages the construction alongside the CERN proton synchrotron of two roughly circular concentric rings about 300 m in diameter which are distorted so that they intertwine, crossing in eight places with an intersection angle of 15°. Pulses of protons will be injected from the proton synchrotron into the rings. Systems of magnets will maintain these injected protons moving in opposite senses round the two rings so that at the intersection regions the two beams of protons will clash almost head on. Many hundreds of pulses will be injected into each ring until a circulating current of up to 20 amp will be stored in each and it should be possible to maintain these stored beams of protons for a day or more.

The great attraction of clashing beams stems from the fact that in the interaction between two protons, one in either beam, the mass centre of the two particles is almost at rest so that the resultant total momentum of the system is small. This is in contrast to the situation in a conventional accelerator where interactions occur between one energetic and one stationary particle. Since in the final system the total momentum of the products has to be the same after as before the interaction, the greater part of the energy, in the case of particles accelerated in a conventional accelerator, has to go in providing this momentum. In the intersecting storage rings, on the other hand, almost the whole of the energy will be available for producing nuclear interactions.

The total energy of about 56 GeV that will be available in the intersecting storage rings should therefore produce interactions between protons which, for a conventional accelerator, would require an energy of 1,700 GeV. On present indications a conventional machine of such a high energy seems unlikely to be built within the next generation, if at all Although the collision rate obtainable in the intersecting storage rings will be much smaller than that for a conventional accelerator of equivalent energy, the estimated rate of 10^5 interactions per sec is as much as can comfortably be handled with the types of detection techniques suitable for use with this system. Indeed, for many experiments it will be advantageous to operate with a smaller circulating current.

The construction and operation of the intersecting storage rings will present some challenging technical problems. In the kilometre-long tubes that carry the beam a pressure not greater than 10^{-9} mm of mercury will have to be maintained, while in the neighbourhood of the intersections the pressure will need to be kept down to at most one-tenth of this. In the course of the time during which the beams will frequently be stored the protons will traverse a distance hundreds of times as great as that from the Earth to the Sun. While traversing this great distance they will need to be confined within a tube with a maximum cross-section of 16 cm.

The very magnitude and novelty of the technical challenge are only slightly less exciting than the physics which will be made possible when these problems have been successfully overcome. Nobody has any real doubt that they will be overcome. The team that has been working on the design of the intersecting storage rings and will be responsible for the technical supervision of their construction embraces a quite unique range of experience, technical know-how and capacity for daring innovation.

The substantial increase in effective interaction energy which will become available as a result of the construction of this machine should yield information of great significance for the solution of some of the most fundamental problems relating to the nature of matter and of interactions between particles of great energy and at very small separations. The range of new physical phenomena revealed by experiments with existing accelerators has proved to be unexpectedly rich. The lines of the interpretation of these phenomena have been suggested, but decisive tests of these interpretations seem likely to be possible only when much greater effective interaction energies are available. This is the case in the investigation of the so-called strong interactions—which include the class of interactions responsible for the stability of atomic nuclei—where there is evidence to suggest that the striking symmetries that have been recognized in the past few years may perhaps be understood in terms of the existence of three kinds of very massive primeval particles (quarks). The isolation of these quarks, would, however, require interaction energies much greater than those available from any existing accelerator.

It is also the case in the investigation of the weak interactions—which include the class of interaction responsible for β-radioactivity—where the available experimental evidence strongly suggests moderation of the interaction through the so-called W particle (or inter-

mediate boson) of mass too large to be produced with presently available accelerator energies.

The actual experimental programme of the CERN proton synchrotron has proved very much more diverse and interesting than any that was predicted for it when it was being planned in 1954. This is likely to be the case also for the intersecting storage rings. Nature is far richer than the mind of the most imaginative physicist can foresee.

Experimentation with the intersecting storage rings presents problems of great difficulty. It will be necessary to develop detectors with better time resolution than is generally available at present, capable of operating under conditions where many particles are produced in the same interaction, and of discriminating between colliding beam interactions and interactions with the background gas. Considering the pace of technical development, however, these difficulties do not seem more daunting than others that have already been successfully solved in the field of high-energy physics instrumentation.

The cost of the intersecting storage rings is estimated at approximately £28 million spread over 6 years. It will involve an increase of about 35 per cent in the CERN budget, one-quarter of which is covered by the British contribution. This extra expenditure has, however, to be measured against the returns it will bring in the form of an extension of the useful working life of the CERN laboratory throughout the period 1970–80 when it should be in a position to make a unique contribution in this field of study that could be made neither by the 70-GeV proton synchrotron of the Serpukhov Laboratory in the U.S.S.R., due to come into operation at the end of 1967, nor by the 200-GeV United States machine which is expected to be operational by 1972 or 1973. Judged from the point of view of its role in maintaining a centre of excellence in high-energy physics research in Europe, it appears to be an imaginative and worth-while investment.

It is most gratifying that firm commitments to proceed with the construction of the intersecting storage rings came just prior to the retirement of V. F. Weisskopf from the post of director-general of CERN. During his period of office, Weisskopf worked tirelessly to impress on the appropriate authorities in the member States of CERN the need for long-term planning of the future European programme in high-energy physics. His initiative and enthusiasm led to the setting up in 1963 of the European Committee for Future Accelerators under the chairmanship of E. Amaldi. With the agreement on the intersecting storage rings, the first part of the programme recommended by this Committee is in the process of being implemented. The second, even more important and certainly much more costly part of the programme recommended by this Committee, the construction of a 300-GeV proton synchrotron in Europe, is still being studied. The intersecting storage rings are in no way an alternative to such an accelerator, because the latter can also produce beams of energetic mesons and other particles which are a very important additional experimental resource for high-energy physics. For the production of such beams, the motion of the centre of mass in proton–proton collisions is an essential advantage, as it provides much of their energy. In view, therefore, of the complementary nature of the two parts of this programme, European high-energy physicists will hope that a favourable decision on this other part of the programme will not be too long delayed.

HIGHER EDUCATION IN BRITAIN

THE debate on higher education in the House of Lords on December 1, which was opened by Lord Robbins, did not re-examine the question of the scale of university expansion, except in so far as to express doubts about whether the agreed target could now be achieved, in view of the 6 months standstill imposed on new university building. This standstill; as Lord James of Rusholme promptly pointed out, in practice meant a delay of at least a year. The question of organization, which had been the other main theme of the debate in December 1963, was again to the forefront, and Lord Robbins strongly attacked what he termed the 'binary system' set up in the Ministry of Education and Science by the Government. The other two main topics of the debate were the development of the colleges of advanced technology and the position of the teachers' training colleges.

Lord Robbins questioned the wisdom of the decision that no new universities, beyond the six recommended by the Committee on Higher Education, should be created during the next 10 years, and suggested that this decision might create difficulties for forward planning in later years. He was more concerned, however, that the assumption of university status by the colleges of advanced technology might be accompanied by a change in work or function as well as position. He emphasized the vital importance of their continuing to develop on their existing basis and in this he received strong support from Lord Kings Norton, who insisted that the preponderating position of the sandwich course must be maintained, as well as the collaboration between industry, commerce, the professions and the teaching staff.

Lord Robbins's other anxiety concerned the teacher training colleges, and he argued strongly, as did the report of his committee, that the administration of the colleges should be transferred to the universities. He thought that this question of status could be of vital importance in ensuring that an adequate supply of candidates of high ability was forthcoming; he regarded the failure to implement this recommendation as an outstanding weakness of the new binary system. Lord Robbins did not receive general support in this view, though he was strongly supported by Lord Murray of Newhaven. Lord Murray was also concerned about the effect of centralizing administrative arrangements in the Department of Education and Science on higher education and research generally. He was disturbed at the possibility that complete absorption of the universities and the research councils in one Ministry might prejudice the development of higher education as well as research. Lord James of Rusholme, although he supported the idea of a single Ministry, strongly attacked the financial policy which the Government had in practice pursued towards the universities. He insisted that the financial arrangements required overhaul and, while willing to accept closer financial controls, emphasized that such controls must provide security and flexibility. His argument was strengthened by a powerful aside in pleading for adequate finance for

university libraries, which at the lowest were as essential as laboratories or apparatus.

Lord Snow, conceding the crucial importance of academic freedom, was more optimistic as to the possibility of achieving it within the framework of existing arrangements, particularly if information was distributed effectively. He defended the binary system, and in his reference to the teachers' training colleges went a long way towards accepting Lord Robbins's argument. On the question of strengthening the University Grants Committee he was silent, and although Lord Robbins's original plea here was taken up by Lord Hankey and Lord Sherfield, and particularly by Lord Annan, who made several constructive suggestions, it received no comment from the Earl of Longford, who concluded for the Government. Lord Todd also was dubious about the Government's financial arrangements for university building, but the main point in his speech related to the use of television, particularly in the development of what had been described as a 'university of the air'. He thought that there were three educational objectives of major importance which should receive priority at this time. First, there was the provision of school courses in science and mathematics to offset the present shortage of teachers of these subjects; secondly, the provision of courses in science and technology for re-education and training; and thirdly, the development of extra-mural education by the universities.

Lord Todd thought it was in regard to the two last-mentioned objectives that television had a vital contribution to make. If the problems of technical training and adult education were to be tackled, the universities and colleges of technology would have to play their part, and for this they needed a 'university of the air'. Lord Todd was supported by Lord Annan but, while the Earl of Longford confidently affirmed the Government's belief that the target figures of 218,000 university places in 1973–74 would be achieved despite the fact that building starts for 1967–68 and 1968–69 had not yet been agreed, on the 'university of the air' he said no more than that all the implications were being carefully considered. He thought that a 'university of the air' would need a substantial share in a television channel with national coverage. He agreed, however, that the University of Strathclyde could play a useful part in any national scheme by training staff and by preparing and producing programmes that could be transmitted nationally. He declined to commit himself as to licences for low-powered transmission by this or other universities. He did not reply to Lord Wynne-Jones's observation that the estimates in *The National Plan* provided for only 170,000 university students by 1970 and not 199,000, nor was he forthcoming as to alternative sources of university finance, such as higher fees or student loans which had been mentioned in the debate. On the colleges of advanced technology, he merely said that the Government recognized that the National Council for Academic Awards had a major part to play in shaping the future of the technical colleges as centres of higher education.

The impression of 'woolly' thinking on the part of Government spokesmen in this debate is strengthened, rather than otherwise, by some of the papers contributed to the symposium on "The Modern University" at the University of Strathclyde in November. Sir Denis Brogan, dealing with "The Democratic University: American and British", and Dr. Magnus Pyke, discussing "Universities in the Modern Age of Scientific Understanding", dealt with some of the wider issues which had been raised in the debate in the House of Lords. Dr. Pyke made a powerful plea that the universities should endeavour to produce the 'all-rounder' as well as the specialist. Prof. S. G. E. Lythe also gave a firm warning against yielding to professional pressure, and maintained that the first task of a modern university was to ensure that all its graduates had experienced a rigorous intellectual discipline in one field of investigation in which they have penetrated to fundamentals. G. E. Hartley offered some wise words about research and teaching and about the danger of forgetting that only a few students eventually become university teachers; while I. F. Clarke insisted on the importance of a broad curriculum.

One significant characteristic of the local contributions to the symposium was the way in which they pointed to practical means of increasing efficiency or diminishing the costs of university education by attention to points which, possibly trivial in themselves, could in the aggregate be considerable. Mr. E. W. Hughes, of Newcastle upon Tyne, spoke on "New Patterns in University Organization" and was followed by a very practical contribution from Mr. L. McGougan, "A Philosophy for University Administration". The contributions on library services and students' book grants, and notably Mr. W. Scott's paper on "Technological Services in a Technological University", were characterized by a like valuable pragmatism. It would seem from this symposium that the possibilities of increasing efficiency are far more clearly grasped within the universities than by the Government. This was very conspicuous in the papers from K. J. W. Alexander, on "The University and Adult Education", and from A. Ward on "The University of the Air". Such arguments as were put forward were by no means disposed of by the Earl of Longford in the House of Lords debate or by what was added in a written answer in the House of Commons on December 21.

The existence of serious concern over the Government's attitude to the universities was even more apparent in a later article by Lord Robbins in the *Universities Quarterly*. Such concern is also reflected in the report of the Flowers Committee, in the annual survey of the University Grants Committee for the academic year 1964–65*, and in some remarks of Dr. W. H. F. Barnes, vice-chancellor of the University of Liverpool, at the annual meeting of the University Court. Immediately before the Christmas recess, on December 21, the Secretary of State for Education and Science, Mr. A. Crosland, did announce that the Government accepted the recommendations of the Flowers Report, but proposed to spread the expenditure over 6 instead of the 5 years recommended. Little else emerged to remove the misgivings expressed, and the argument for the five essential freedoms of the universities could not well have been better expressed than by Dr. Barnes.

Dr. Barnes agreed that the universities must expect to account to the Government for the expenditure of the large sums voted to them. They must, however, remain free to select their staff and choose their students, to determine their degrees and standards and courses for undergraduates, to decide on their own research programmes and to allocate their financial resources. Dr. Barnes insisted in particular that universities should not accept the extreme thesis that their function was to supply graduates in the proportions required by the latest economic blueprint. He was also concerned that variety in sources of financial support should be encour-

* University Grants Committee—*Annual Survey, Academic Year 1964–1965*. Pp. 15. Cmnd. 2846. (London: H.M.S.O., 1965.) 1s. 6*d*. net.

aged, particularly if the freedom of a university to decide on its own research programme was not to be affected by over-dependence on grants from research councils or from industry.

Apart from the final emphasis on the difficulties and uncertainties which the building deferment policy inevitably involves in the expansion of the universities to meet the Government's objectives and in the arrangements to be made for the next quinquennium, the University Grants Committee in its annual survey only touches on its differences with the Government in muted terms: the frustrations and anxieties are obvious but are allowed to speak for themselves. The Committee, however, is in full agreement with the concept of a dual system of higher education, with each sector—the autonomous and the public—making its own contribution. The Secretary of State for Education and Science developed this idea in a speech at the Woolwich Polytechnic on April 27, 1965, and has discussed its implications with the Committee of Vice-Chancellors and Principals. It regards the Minister's decision not to support the proposed integration of the Lanchester College of Technology at Coventry with the University of Warwick, while encouraging the closest possible academic co-operation, as giving a guide for the practical application of the policy of the dual system.

On university expansion and building programmes, the Committee decided to make an immediate allocation among the universities of the £33 million for building starts in 1966–67, but to postpone the allocation of the provisional £25 million for each of the following two years until it had completed the investigations and discussions necessary to establish final figures for these 2 years. The Committee foresaw considerable difficulties, both for itself and for the universities, if decisions about the priorities of particular building projects had to be taken in relation to allocations which might later be significantly altered to take account of under-capitalization and obsolescence. The Committee is grateful to the universities for their response to the request for a detailed return of the total amount of accommodation available, or expected to be available, by 1967–68, together with an assessment of the suitability of buildings for continued use for university purposes. Owing to such co-operation in this massive and laborious operation, the University Grants Committee was able to submit in May a comprehensive analysis of the whole accommodation available by 1967–68 in relation to the student population at that date and the extent of the deficiencies which it would be necessary to make good. The analysis was discussed with the Department of Education and Science, but the discussions had not been concluded when the Chancellor of the Exchequer announced the Government's economic measures on July 27. Since then, the University Grants Committee has been ascertaining from the universities the precise effect of the deferment policy on their building programmes for 1965–66 and has discussed with the Department of Education and Science the extent to which exemptions from the general rule may be considered in particular cases and the repercussions of the deferment policy on the allocations of building starts for later years.

The Committee and its Medical Sub-Committee were much concerned during the year with planning measures to increase the student intake of the medical schools. There is still a large gap between the actual annual intake and the intake which would be needed to correct the increasingly critical shortage of doctors—the present bottleneck being at the preclinical stage. In the present financial situation there is no prospect of embarking on a comprehensive programme of modernization, but the Committee has been invited to submit evidence to the Royal Commission on Medical Education, under the chairmanship of Lord Todd, appointed on June 29. Arrangements have been made to carry forward the planning for the new Medical School and Teaching Hospital at Nottingham where the Committee has already given financial assistance towards the initial cost of the staff and the development of the library.

The University Grants Committee was also asked to advise on the additional provision of a recurrent grant which it would be appropriate to make during the last 2 years of the present quinquennium to continue the build-up of the Imperial College of Science and Technology, the Manchester College of Science and Technology and the University of Strathclyde, while encouraging and expanding promising developments in the technological departments of other universities. Supplementary recurrent grants totalling £1 million for 1965–66 and 1966–67 were announced on June 29 for allocation to these three institutions to rectify certain serious deficiencies in technology, to consolidate existing activities, and to support selected important projects which were developing out of existing activities. At the same time, the Government indicated that it intended to make available up to £400,000 over the same period for selected approved technological projects in the remaining university fields. The Committee has also advised on the recurrent grant requirements of the colleges of advanced technology for these 2 years and on proposals for the acquisition of additional sites for development submitted by the Birmingham College of Advanced Technology and the Bradford Institute of Technology.

The remaining matters with which the survey is mainly concerned are the comparative analysis of university costs and the control of capital expenditure. On the former, the Committee has become increasingly conscious of the need to obtain more detailed information about university costs and to develop improved techniques of comparative analysis. The Working Party set up in March 1965 under the chairmanship of Sir Harold Sanders "to review the content and layout of the financial and other returns submitted to the University Grants Committee by universities with a view of improving them as instruments of comparative analysis of university past and projected expenditure" has already reported, and the University Grants Committee has accepted its recommendations. The Committee has also discussed the proposed new arrangements with representatives of the Committee of Vice-Chancellors and Principals.

The Working Party agreed that the essential basic requirements for the purpose of comparative analysis were to separate expenditure on research and to calculate an undergraduate unit cost. This would necessitate separating and quantifying, on a consistent basis, the cost of undergraduate teaching, the cost of postgraduate work, and the cost of research carried out by university staffs. The Working Party recommended, accordingly, that revised forms of return should be issued to universities for completion in respect of the academic year 1965–66, and that the operation, once introduced, should be a continuing one, though the arrangements might need to be revised and adjusted in the light of the first year's working. The universities have agreed to put these arrangements into operation for 1965–66, subject to further discussions on the precise techniques to be used. They have reservations, however, about the reliability of

the information in the form in which it is sought, particularly as regards the division of effort between teaching and research, and about the use of the information when it becomes available.

In the light of the study made by the joint Working Party, set up by the Committee and the Department of Education and Science, to review the existing arrangements for controlling the cost of residential accommodation in institutions of higher education, the Committee and the Department concluded that there was no justification for any variation in standards between residential accommodation in universities, colleges of advanced technology and colleges of education. It believed that a single-cost system, flexible enough to deal with the varying requirements, was both possible and desirable. The revised system recommended by the Working Party is in essence a refined version of the previous system, operated on the basis of a 'study–bedroom unit' and designed to retain and increase the flexibility allowed to universities and their architects. The new arrangements were conveyed to the universities in April 1965; essentially they apply to all residential schemes programmed to start in 1965 and subsequent years for which cost lists have not already been fixed.

A joint Working Party with the Department of Education and Science has also been set up to review the cost–control procedures applying to academic buildings where the problems are far more complex. The requirements for teaching and research vary from one university or department to another, and with science buildings a wide range of specialized services has to be covered. The Working Party is accordingly proceeding by stages, starting with the simpler types of teaching and office building. In order to encourage the application of industrialized building techniques to university buildings, the University Grants Committee and the Department of Education and Science are collaborating with the Bristol College of Science and Technology and its architects in developing and applying the 'C.L.A.S.P.' system of construction [see *Nature*, 209, 768; 1966] to increase its suitability for science and technology buildings. The Committee has also been giving much attention to developing a system of monetary allowances which would serve as 'norms' for assessing the value of the equipment needed in new university buildings, both for teaching and for research. The present arrangement is laborious and time-consuming, and it would simplify the Committee's control procedures if monetary allowances could be worked out in relation to the subjects concerned and to the numbers of students and staffs in the new buildings.

The Committee is also conscious of the serious problems which face universities in replacing and modernizing equipment in existing buildings. The problem of financing university purchases of equipment has been comprehensively examined by a joint Working Party of officials of the Committee, the Department of Education and Science, the Treasury and the Science Research Council. The report of this Working Party is now under consideration, and a Working Party of officers of the Committee and of the Ministry of Public Building and Works is examining how the use by universities of the Ministry's facilities for the supply of furniture can be encouraged and extended.

The survey makes no comment on the report of Prof. B. H. Flowers' Working Group on the supply of computers beyond stating that the Committee considered it and passed its views on to the Government at the beginning of August. The two things that stand out from this survey, however, are, first, the extent to which Government policy has itself enhanced the difficulties and uncertainties of the University Grants Committee, and secondly, the persistent failure of the Government to strengthen the Committee's powers to discharge its growing responsibilities. Part of the pressure on the Committee is directly of the Government's making and could be removed by a consistent policy on the part of the Government. Part, however, is the direct outcome of the Committee's steadily increasing responsibilities.

The survey shows how admirably the Committee is itself seeking to meet the new situation and to face new and legitimate demands. It substantiates all that was said in the Robbins Report and has been reiterated in Parliament as to the imperative need to strengthen the staff of the Committee. The Department of Education and Science, however, on which the main responsibility for the failure to strengthen the Committee must fall, does not present such a satisfactory picture. Doubts as to the wisdom of placing the University Grants Committee under the Department of Education and Science cannot but be raised by the frequent references to that Department in this brief survey, especially in the absence of any positive action by the Department to strengthen the Committee or of evidence of a real understanding of the problems of university expansion and development on the part of the Minister himself. Co-operation with the Department of Education and Science there must clearly be, but without including a word of criticism this survey cannot but raise serious misgivings in the universities and elsewhere as to Government policy in higher education. If the debate in the House of Lords on December 1 was largely inconclusive and somewhat disappointing, any subsequent debate that may take place in the House of Commons in the light of this annual survey is likely to be far more incisive and could well be extremely disconcerting for the Department of Education and Science.

POLITICAL AND PHILOSOPHICAL IMPACT OF SCIENCE

Science as a Cultural Force

Edited with an Introduction by Harry Woolf. (The Shell Companies Foundation Lectures.) Pp. viii+110. (Baltimore, Md.: The Johns Hopkins Press; London: Oxford University Press, 1965.) 32*s*. net.

THE four lectures collected in *Science as a Cultural Force* fall neatly into two groups : the administrative and the philosophical. The first two lectures by former science advisers to the President of the United States are concerned with the challenge from without, repeatedly identified as the fact that the U.S.S.R. is producing twice as many scientists as the United States. But their main preoccupation is with the challenge from within: the new pattern of relations that is emerging between the Government and the scientific community. Dr. James R. Killian believes that the executive branch of the Government should make a greater use of scientists in policy-making and in the co-ordination of scientific activities. There is increased governmental pressure resulting from larger grants to universities for research, and the consequent danger of unwittingly imposing constraint on the creative process on the one hand. On the other, society as a whole is becoming more and more research-conscious and research-reliant. This entails the risk that every state, every district, will consider itself thwarted if it does not have its own research centre. These problems must be faced by the scientists themselves. Their traditional fear of overarching bureaucracy has kept them

aloof, but they can no longer elude the fact that the problem of priorities and the political pressure for geographical distribution of Government funds are likely to mean more politics in science. Somehow they will have to learn to work effectively in the political arena.

This leads to the question of the allocation of public funds. How is the State to distribute money for research? Or rather, how is the scientist to enlighten the politician on the research that is important but that yields no immediate results? This is by no means an easy task if we believe Dr. Jerome B. Wiesner. As a Special Assistant to President Kennedy, he was confronted with angry demands to explain how particular pieces of research could possibly be useful. The problem lies in the fact that while the research scientist is primarily motivated by an urge to explore and understand, society supports him primarily because experience has demonstrated how essential research is for the continuing progress in technology. The trick would be to convince down-to-earth Congressmen that acquiring scientific knowledge is a form of capital investment. They might be willing then to consider Dr. Wiesner's proposal that the United States spends a billion dollars on fundamental research, which, after all, would still be less than 20 per cent of the space budget.

The third lecturer, Dr. Michael Polanyi, raises the discussion to the philosophical level when he argues against the ideal of scientific 'detachment'. His two contentions are that all knowledge is based on a measure of personal participation and that we know more than we can tell. The evidence he adduces are cases of 'subception', when an individual becomes aware of an anomaly and subconsciously reacts to adjust himself to its requirements. Whether we can conclude from these examples that knowing is indwelling is open to doubt. So is the claim that the explanation of all living processes by physics and chemistry collapses unless we deny altogether the existence of consciousness. It is, of course, impossible to do justice to such topics in a lecture or a short brief essay. Yet they may whet the reader's appetite and entice him to look up what Dr. Polanyi has written about this elsewhere.

Dr. Gerald Holton tries to bridge the gap between science and the humanities by showing that a simple-minded view of the inductive process (which he seems to identify with the hypothetico-deductive method) is misleading. In order to understand how scientific theories are constructed we must be aware of the presuppositions that underlie them. To empirical and analytical statements, which he likens to x- and y-axes, Dr. Holton adds a third or z-axis. This is the dimension of the fundamental propositions, notions, terms, methodological judgments or decisions—in short, the themata or themes that underpin and penetrate a scientific explanation. This thematic analysis has been fruitful in other fields and it is only recently that it has attracted the attention of the historians and the philosophers of science. Possible examples would be the heuristic concept of 'force' in physics, or the pervasive laws of conservation. This kind of enquiry would help us to a view that goes beyond the usual antithetical juxtaposition between science and the humanities. The lamented separation between science and the other components of our culture depends on the oversimplification which implies that science is done only in the contingent plane, whereas scholarly or artistic work involves basic decisions of a different kind, with predominantly aesthetic, qualitative, mythical elements. In Holton's view, the dichotomy is attenuated, if not eliminated, if we see that science, too, needs more than the contingent plane. But what is there beyond the contingent that is more than a merely provisional absolute? The thematic analysis that is suggested is becoming increasingly common, but we have yet to be told how themes are to be compared, and according to what norms.

W. J. Shea

SOCIAL IMPLICATIONS OF EDUCATION

Education and Values

Essays in the Theory of Education. By G. H. Bantock. Pp. 182. (London: Faber and Faber, Ltd., 1965.) 25*s*. net.

Educational Values in an Age of Technology

By F. B. Pinion. (The Commonwealth and International Library of Science, Technology, Engineering and Liberal Studies. Education Division, Vol. 1.) Pp. xi+184. (London: Pergamon Press; New York: The Macmillan Company, Ltd., 1964.) 17*s*. 6*d*. net.

LIKE G. H. Bantock in the essays collected under the title *Education and Values*, Mr. Pinion is concerned with educational and other values, but what the two books have in common both with Dr. Michael Young's *Innovation and Research in Education* and with Mr. F. C. Palmer's little book on *Student Guidance* is very striking. It is perhaps not surprising to find Mr. Palmer's insistence on the importance of the teaching of English reflected in one or two of Mr. Bantock's essays and in different context by Mr. Pinion. More impressive is not merely the insistence on the importance of more research into education in all four books but also the emphasis on the social implications of education and its place in modern society. Moreover, it is not just an expansion of educational research that is urged: searching questions are asked about its nature and the methods of investigation as well as the choice of subjects.

This consensus of opinion, if not altogether unexpected, is encouraging. Mr. Bantock discusses educational research in only one of his eight essays, but, even so, in that essay his criticism endorses much of Dr. Young's thesis, while elsewhere he enters more fully into some of the characteristics of society to-day from which that thesis is developed. He demonstrates how the facing of questions of values stimulates fresh thinking about the content of curricula as well as about methods of teaching, and that the decisions we take as to values determine the appropriateness of our whole educational system for this age of technology. It involves considering afresh the different roles which the arts and sciences fulfil in developing the complete human being. Nor can our decisions on values be wisely made without regard to the relations between school or university and the community, and the value we place on the individual. Just as firmly as Dr. Young or Mr. Palmer, he challenges accepted principles and preconceived ideas and stimulates fresh thought about the moral issues involved, and how the needs of a technological and changing society are to be reconciled with the development of human personality. Again, like Dr. Young and Mr. Palmer, he maintains that learning remains the most vital prerogative and task of our schools.

Mr. Bantock, nevertheless, realizes that an education concerned simply with a social justice limited to economic purposes would be imperfect, and he makes his point in the context of technological and technical education. Mr. Pinion is more especially concerned with these subjects, though his warning against obsession with class and opportunity interpreted in political terms is given also in a discussion of education, social justice and sociologists. It, too, is reflected by Mr. Pinion, particularly in reviewing the general problems in educational organization, where he comments trenchantly on the influence of class prejudices and emphasizes the need for safeguards. "Education", he observes, "is too precious and costly to be the shuttlecock between opposite political parties".

Educational Values in an Age of Technology is in two parts. The first part is essentially a factual appraisal of the situation in Great Britain. Besides the chapter just noted in which he refers to such diverse matters as administration, the supply of teachers, curricula reform, examinations, finance and research, it includes separate chapters on the growth of technology, the schools, the universities

and colleges of advanced technology, and on other forms of further education, which he reminds us are for many more appropriate than either a university institution or a college of technology. The second part, which occupies less than 50 of his 180-odd pages, is more philosophical and exploratory. Its three chapters, on the cultural crisscross, on the limitation of intellectualism, and on science and religion, seek to outline the dilemma in which the rising generation is placed by the steady erosion by specialization of the areas of agreement and mutual understanding.

Even the factual survey is packed with sense and constructive suggestions and makes a useful contribution to any discussion on the impact of science on society which does not make comfortable reading for those responsible for policy. He has no use for policy which is not determined on educational grounds but by political ideology. Mr. Pinion has an eye for the essentials and is every bit as forthright as Dr. Young in condemning the waste of resources on trivialities and in asserting the need for fresh and unprejudiced thinking. It is, however, above all in what he writes, in his second part, about communication between scientist and non-scientist and on the limitations of intellectualism that he is most challenging. In contrast to Mr. Bantock, who has reservations regarding technology, he has, like Sir Eric Ashby, a deep sense of the value of science and of technology as cultural elements themselves, and his final chapter on science and religion is outstanding in its insight and balance. The greatness and value of science are that, besides teaching us the wonders of creation, it also, seen in the perspective of its conclusions, gives us a sense both of man's power for good and of his fallibility and weakness. Science and religion, in Mr. Pinion's view, can meet, but both must adjust their attitudes. His book is well written as well as stimulating and his wide and apt quotations are supported by an admirable reading list. Fully as effectively as either Mr. Bantock or Dr. Young, he brings us face to face with some of the vital issues with which the advent of compulsory education and the prospect of universal literacy has confronted civilization for the first time within the past hundred years. He points alike to the need for fresh thinking and enquiry if the issues are to be resolved in terms of respect for human personality and on the basis of fact rather than fiction or prejudice.

R. BRIGHTMAN

GEOGRAPHY OF THE ICE AGE

Environment and Archeology

An Introduction to Pleistocene Geography. By K. W. Butzer. Pp. xvii+524. (London: Methuen and Co., Ltd., 1965.) 84*s*.

ENVIRONMENT and Archeology is an attempt to show how the geography of the Pleistocene period may be reconstructed and to illustrate the extent to which such reconstruction is at present possible. Part 1 is introductory and largely concerned with the abnormal nature of the Pleistocene, its extent in geological time and the present state of success in dating it in absolute terms. Part 2 is concerned with the interpretation of vegetation, soils and landforms in terms of climate, Part 3 with the interpretation of sedimentary evidence, Part 4 with the interpretation of biological evidence, mostly pollen and macroscopic plant analyses and studies of mammalian faunas. Part 5 is a series of reconstructions mostly of the Late Pleistocene geography of different regions with a natural bias towards the Mediterranean and African areas with which the author is most familiar. Part 6 is virtually a series of essays on aspects of prehistoric human geography.

It may be appreciated from the foregoing summary that the field attempted is vast, and this is the source of both the strength and weakness of the work. No one Pleistocene specialist will attempt to cover more than one or at most two specialized aspects: he may be a 'beetle man' or a 'snail man' but rarely both; he may be a 'plant and landform man' but not a 'plant, landform and mammal man'. Thus, any synthesis such as this must place a great deal of reliance on secondary sources, on review papers and on the standard teaching manuals on landforms, soils and vegetation. This is inevitable, but it does lead in places to an air of certainty which the specialist would probably disclaim. Practically all questions on such subjects as the origin of landforms and the precise controls of plant and animal species distributions are open ones. But when such evidence is used in palaeogeographic reconstruction one particular interpretation must be chosen for each line of evidence and the interpretation of one piece of evidence may be conditioned by that already put on another. The result may be a sum of truths or a sum of errors, or more commonly a mixture. Perhaps it would have been better not to have attempted to teach the skeletal and hence seemingly dogmatic treatments of soil science, climatology and geomorphology of Part 2, but to refer the reader to reference works for systematic information and to discuss more fully the interpretative doubts.

Yet the apparent dogmatism is conditioned more by the telescoping necessary to cover the field than by any lack of critical appreciation on the part of the author, who deals critically with such vexed questions as the differences between modern and Pleistocene periglacial climates consequent on the different latitudinal positions, with the possibility of the vegetation succession being either climatic or edaphic and with many other awkward problems. Perhaps he relies more on vertebrate evidence, which is subject to human as well as to physiographic controls, than on the invertebrate evidence of such creatures as beetles and snails, which more nearly reflect only physiographic controls—but this may only be a difference of taste between the author and myself. All in all, the book is very valuable and very welcome. In a period when Pleistocene investigations, like many other branches of knowledge, are in danger of disintegrating into mutually semi-comprehensible specialisms, it performs the invaluable constructive and difficult task of synthesis. As such, it should be received with praise and charity by undergraduates, researchers and all interested in the fascinating field of Pleistocene geography.

B. W. SPARKS

EQUILIBRIA IN IRON AND STEEL MAKING

Phase Equilibria Among Oxides in Steelmaking

By Prof. Arnulf Muan and Prof. E. F. Osborn. Pp. xx+236. (Reading, Mass.: Addison-Wesley Publishing Company, Inc.; London: Pergamon Press, Ltd., 1965.) 135*s*.

IN any long-established industry there is a well-defined art which, as knowledge increases, develops into a science. The art exists because it is successful and, although it may have complexities based more on tradition than on logic, the majority of the practice has evolved from sound, factual experience. Following as it does on the art, the science is not always received as enthusiastically as the scientist may desire: this arises, partly, from the difficulties of communicating the use of new ideas to technologists whose training has preceded the advancement of the science. Furthermore, it can happen that the facility to manipulate scientific data is lost in a disastrously short time by the scientist working in industry. Any attempt to overcome these difficulties in converting an art to a science is laudable, but the task is difficult, criticism is freely given, and failure is fairly easy.

The American Iron and Steel Institute has for some years sponsored investigations of phase equilibria in

steel-plant refractories in the College of Mineral Studies at the Pennsylvania State University. The College has made many original contributions to this subject since the project started in 1949 : this work has, in one sense, culminated in the publication of the book, *Phase Equilibria Among Oxides in Steelmaking*. The authors, Profs. Muan and Osborn, have aimed to bring together all available data on relevant oxide systems, and to apply this scientific information to process problems in the iron and steel industry. The presentation of the information has been designed for use by those meeting these problems as they assist in practising the art of operating the production plants.

The first three-quarters of the book gives data relating to equilibria in some sixty oxide systems of importance in iron and steel making, and sets out the basic principles underlying the information. This part of the book is excellent. No attempt is made to over-describe the basic science of the subject, references being given to many of the excellent texts already available: the essential principles are made clear by reference to the equilibria in the different types of system discussed. The special interest of the authors in this part of the work may be clearly discerned; more than three hundred original references are cited, and the subject is treated in an objective and critical manner. Whenever possible, the information is presented in a standard diagrammatic form, and the authors have redrawn many published diagrams in order to give a commendably uniform presentation. The diagrams are, in general, clear, but some of the more complex illustrations would benefit from the use of colour, a device which would, unfortunately, increase the price of an already expensive book.

The three final chapters of the book deal with the application of the equilibrium data to slags, oxide inclusions, and refractories. As in the preceding chapters, the information is handled in a clear and constructive manner ; bearing in mind the audience at which the book is aimed, however, these sections do not maintain the high standard set by the earlier chapters. A few slag systems are discussed in reasonable detail, but more examples would have helped the average reader to extend the treatment to other systems. The validity of this criticism is emphasized by the authors themselves, when they point out that many simplifications and assumptions are necessary in order to discuss the chemistry of steel-making slags. Similarly, the logically presented information on oxide inclusions could have been extended, with benefit, to make more clear the ways in which the different phase relationships can affect the morphology of the precipitates.

Despite these criticisms, however, the book will be of undoubted value to those involved in the practical problems of iron and steel making. It should also find considerable use in providing examples for the amplification of university courses dealing with problems of high-temperature equilibria. D. S Oliver

SKIN AND HAIR—A FORWARD-LOOKING PROSPECT

Biology of the Skin and Hair Growth

Edited by A. G. Lyne and B. F. Short. (Proceedings of a Symposium held at Canberra, Australia, August 1964.) Pp. xi+806. (Sydney: Angus and Robertson, Ltd., 1965.) A.210*s*.; 21 dollars.

Biology of the Skin and Hair Growth is a large and wide-ranging book. Among the subjects covered are the skin structure of snakes and lizards; the development of feathers and hair; studies of hair growth waves and rhythms in cattle, sheep, rodents and seals; radiation effects on hair; the detailed biochemistry of keratin structure and fibre formation; endocrine effects on fibre growth; and the cytology and morphology of hair follicles.

Inevitably, in a book of 46 chapters, many of which incorporate original work, the quality of papers varies. But the average standard is very high and the overall impression is that each subject is treated authoritatively. The emphasis of the book is on dynamic features of the skin–hair complex rather than on the classical aspects of anatomy and morphology. As with most symposia, complete coverage of the field was understandably not achieved. In this particular case, several important but specialized topics are virtually excluded; for example, the work of Bullough and his associates on the control of cell division in the hair follicle and the epidermis, and the subject of skin transplantation immunity. There has been no attempt to make a general synthesis, but in view of the variety of material presented this might well have proved an almost impossible task. The nearest approach to generalization comes in the opening paper by Billingham and Silvers which deals with some of the important remaining problems of skin biology.

Of the numerous sections deserving comment it may be permissible to sample a few. Papers by Straile and by Priestley and Rudall both suggest that the morphology and rate of growth of hair fibres may be controlled by a 'cellular shunt' mechanism determining which of the cells formed in the follicle bulb enter the hair fibre and which enter the follicle inner root sheath which invests it. Such a mechanism involves the spatial relationships between streams of newly divided cells moving distally from the follicle bulb matrix. These relationships may be determined by changes in the shape of the dermal papilla. This work and the studies of Fraser and of Short, Wilson and Schinckel on the proliferation rate of the follicle matrix cells may together hold the key to a complete understanding of the process of hair growth at the cellular level.

Cohen, by means of an audacious technique involving the transplantation of individual follicle papillae, has carried out a successful experimental attack on the fundamental problem of epigenetic specificity as between the dermal papilla and the epidermis. Chapman has constructed a highly ingenious theory which accounts for the formation of wool crimp by postulating periodic contractions of the follicle-attached pilomotor muscles. However, there still seems on this theory a difficulty in accounting for the situation in certain British breeds of hill sheep. Here the primary fibres (which are all associated with arrector pili muscles) may comprise a mixed population of loosely-crimped and uncrimped fibres, whereas adjacent secondary fibres (which lack associated muscles) are all clearly crimped. One hopes that Chapman will be able to direct his attention to this problem in the future. Different types of hair-growth rhythm and the factors controlling them in a variety of species are thoroughly dealt with in chapters by Chase, Lyne, Elizabeth Johnson, Ebling, Ling, Hutchinson and Hayman. Aspects of blood-flow to the skin are discussed in several papers, and here Molyneux revives, from a new point of view, the subject of arterio-venous anastomoses in the skin and their possible role in thermoregulation. Endocrine effects on hair growth are considered by Rougeot, by Houssay, Epper and Pazo, and by Downes and Wallace. A comprehensive paper by Ferguson, Wallace and Lindner indicates the bewildering complexity of present knowledge concerning hormonal influences on wool growth.

It should be evident, even from this selective discussion, that here is an essential reference book for all workers interested in the fields of skin and hair growth. Others on the fringe, such as endocrinologists, physiologists, pure zoologists, histochemists and biochemists, will find many chapters of value.

The book is very well produced, both editing and presentation being of an unusually high standard.

J. Slee

Comparative Atherosclerosis

The Morphology of Spontaneous and Induced Atherosclerotic Lesions in Animals and its Relation to Human Disease. Edited by James C. Roberts and Reuben Straus, with Miriam S. Cooper. Pp. xxi+426+Atlas of Colour Plates. (New York and London: Hoeber Medical Division, Harper and Row, 1965.) 150*s*.

THIS volume arose primarily under the impetus of a conference on comparative atherosclerosis, and its fifty-six authors are leading investigators in this field.

The primary purpose of the volume was "to ferret out and consolidate valuable knowledge buried amid the welter of accumulated information in the literature. A need was recognized for an authoritative reference which would compile and catalogue this knowledge in logical sequence and accessible form, sharply delineate differences and similarities of the disease in all species of animals, and determine which animals are acceptable as models for the most vital phase of all this research effort, which is the testing of mechanisms and materials to understand, prevent, and/or treat atherosclerotic disease in man".

Observations on more than four hundred species of animals are discussed and co-ordinated in seven principal sections dealing, respectively, with atherosclerosis in swine, birds, rats and wild animals, canines, primates, rabbits and man. The eighth section is devoted to summaries of more general problems such as: (*a*) the histochemistry of spontaneous and experimental arterial lesions; (*b*) the relationship between spontaneous atherosclerosis in animals and man; (*c*) comparison of experimentally induced atherosclerosis in animals with spontaneous human atherosclerosis; (*d*) an outlook which probes the probable future of research in this field.

The professional investigator will undoubtedly profit by the exceptionally clear and well-organized presentation of this immense material. It will permit him to select those animal species which suit his immediate purpose best and help him to find his way across the enormous literature which deals with this important field.

Not the least attractive feature of this 426-page volume are the 672 illustrations, including an atlas of 416 excellent coloured photographs and a meticulously prepared index.

H. SELYE

Canine and Feline Nutritional Requirements

Edited by Oliver Graham-Jones. (Proceedings of a Symposium organized by the British Small Animals Veterinary Association, London, May 1964.) Pp. x+160. (London and New York. Pergamon Press, Ltd., 1965.) 63*s*. net.

THIS volume contains the proceedings of a symposium organized in 1964 by the British Small Animals Veterinary Association, with the object of bringing together information gained by scientific workers in the field of nutrition, and the practical experience of veterinary surgeons.

The book is divided into two sections; the first is mainly theoretical, and contains a review of the growth, development, and chemical maturation of pups and kittens during the suckling period, and leads naturally to a discussion of protein and calorie requirements, and of the problems involved in the design and evaluation of diets. Some special aspects of the nutrition of the cat are dealt with in separate chapters. Two chapters in this section emphasize the importance of the interrelationships between nutrients and between the diet and other factors, as exemplified by investigations of the effects of different diets on the course of *Toxocara canis* infestation in dogs. The section closes with a description of some diets designed for special purposes such as the treatment of obesity and diabetes in dogs.

The second section, on practical dietetics, contains a review of the requirements of Antarctic sledge dogs, including recommendations for the calorie intakes needed for weight maintenance at different work loads. Following chapters contain information about the breeding and rearing, for laboratory purposes, of dogs and cats on standardized diets and tinned foods, and the concluding chapter describes diets in use at Basle Zoo for all canine and feline animals.

P. R. PAYNE

Coincidence Tables for Atomic Spectroscopy

By J. Kuba, L. Kučera, F. Plzák, M. Dvořák and J. Mráz. Pp. xxxi+1,136. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 130*s*.

THIS large work gives essentially a series of tables showing, for the strongest lines of each element, the likely lines from other elements which might coincide in wave-length over intervals corresponding to three ranges for instruments with dispersions 0·5–20 Å/mm. The authors have been most painstaking and one admires their enthusiasm; one wonders, however, whether such a task could not have been handled both in selection and reproduction by computer techniques. The wave-lengths are based on the lists of G. R. Harrison dating from before 1939, and the opportunity has not been taken of making corrections and improvements from more recent investigations. Thus, work during the past few years on rare earth lines (R. N. Niseley, V. A. Fassel and C. F. Lentz, *Spectrochem. Acta*, 16, 863; 1960) and spectral-line intensities (W. F. Meggers, C. H. Corliss and B. F. Scribner, U.S. National Bureau of Standards Monograph 32, 1961) has not been included. In some ways recent advances in spectroscopic technique, particularly the increasing use of gratings to give higher dispersions, have helped to decrease errors in analysis arising from the influence of overlapping lines.

British spectroscopists will be grateful that, although the authors are distinguished Czechoslovakian spectrochemists, the book is in English with only minor difficulties of translation, for example, 'self-inversions', and 'ionisation tension'. As a general guide to spectrochemical procedure in wave-length measurement and a convenient summary for identifying lines, the book will form a useful although expensive addition to an analytical laboratory library.

L. BOVEY

Collected Papers of L. D. Landau

Edited and with an Introduction by D. Ter Haar. Pp. xx+836. (New York: Gordon and Breach; London. Pergamon Press, Ltd., 1965.) 200*s*.

PERHAPS the most valuable feature of this collection of papers is concerned with the nationality of the author. The most important (in fact, the majority) of Landau's published works are presented in this rather large book, all in English and in chronological order. A few outdated or incorrect works are listed, with comments, in an appendix. The introduction consists of a very short biography and a brief indication of the contents of the papers. My only criticism of the introduction is its brevity and not its existence, the need of which the editor seems to doubt. There are few physicists to-day who are not specialists, which surely implies that the majority of us need some guidance through the works of a man of Landau's range of interests. Those who agree with the editor's sentiment can, of course, skip the introduction.

The publishers are quite right in stating that this book is an "essential addition to the shelves of every library", but it is unlikely that many individual workers will wish to acquire it, due to its high price. There is, however, some hope for the impecunious, since the same publishers are introducing a new series of books entitled *Men of Physics*, two volumes being devoted to Landau. The combined volumes will contain twenty of the more important papers and will cost 17*s*. 6*d*. each (paperback).

L. L. J. VICK

OBSERVATIONS OF THE RUSSIAN MOON PROBE *LUNA* 9

By Prof. J. G. DAVIES, SIR BERNARD LOVELL, O.B.E., F.R.S., R. S. PRITCHARD and Prof. F. G. SMITH
University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank

ON January 31, 1966, Tass announced the launching of the Moon probe *Luna* 9. Signals from the probe were acquired at Jodrell Bank on February 1 and on February 2 the observations were transferred to the Mark I 250-ft. diameter radio telescope. From previous information available from the flights of *Lunas* 5, 7 and 8 it was anticipated that the probe would arrive at the Moon during the evening of February 3, an expectation supported by a second Tass announcement that *Luna* 9 would reach the Moon at 22h 00m U.T. on February 3. In the event, the landing of *Luna* 9 on the Moon occurred at 18h 45m. The purpose of this article is to give a short account of the observations made at Jodrell Bank of the landing phase and reception of the television photographs from this first successful landing of scientific apparatus on the lunar surface.

Experimental Arrangement

The receiving system consisted essentially of the Mark I 250-ft. radio telescope working on a frequency of 183·535 Mc/s. The gain of the telescope on this frequency is 40 dB and its beamwidth 2 deg. to half power. The full gain was not realized in this experiment because the telescope was simultaneously engaged on other research programmes and the pre-amplifier had to be placed at some distance from the primary feed involving a cable loss of about 2·5 dB. The pre-amplifier was a *DET*29 grounded grid triode with a 2-dB noise factor. After further amplification the output of the pre-amplifier was converted to an intermediate frequency of 10·555 Mc/s using an oscillator locked by means of a Gertsch *FM*-6 frequency meter to a 1-Mc/s frequency standard with a short-term stability of $\pm 2 \times 10^{-10}$. The 10·555 Mc/s signal was then fed into a Racal *RA*17 receiver. The local oscillator of this receiver had a frequency stability of 2 c/s over 1 min with a maximum excursion of about 20 c/s.

The signal from the 100 kc/s intermediate frequency of the Racal with an 8-kc/s bandwidth was fed to a phase-locked oscillator and by synchronous detection the phase modulation was extracted. The detected phase-modulated signal was recorded together with appropriate time and frequency standards on an Ampex *FR*100*A* tape recorder. The frequency of the phase-locked oscillator, which was proportional to the signal frequency, was measured using a digital counter and printed out automatically every 2 sec. The printed figure was the integral frequency count of the previous 1-sec interval.

The Landing Phase

The variation in received frequency from 17h 50m to 18h 45m U.T. is shown in Fig. 1. From 17h 50m to 18h 44m U.T. the intermediate frequency decreased from 100,932 to 100,638 c/s, representing an increase in the line of slight component of the velocity of 494 m/sec,

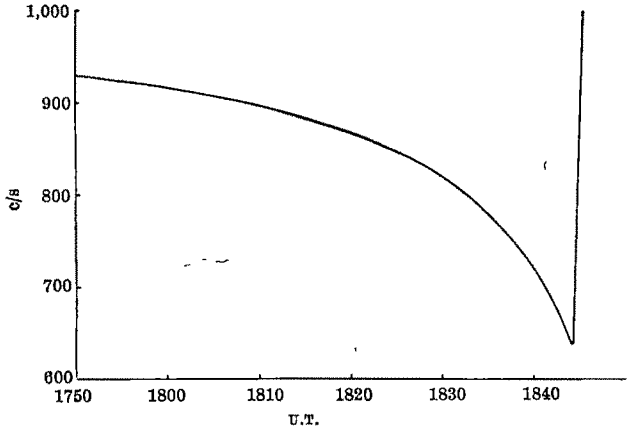

Fig. 1 The variation of received signal frequency from *Luna* 9 between 17h 50m U.T. and 18h 45m U.T. on 1966 Febr. 3 The ordinate is the intermediate frequency minus 100 kc/s Abscissa is time in U.T. on February 3, 1966

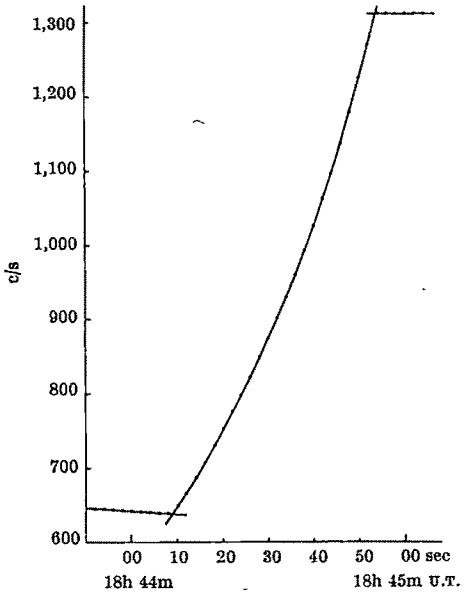

Fig. 2. The variation of received signal frequency from *Luna* 9 between 18h 44m U.T. and 18h 45m U.T. on 1966 Febr. 3. The ordinate is the intermediate frequency minus 100 kc/s. Abscissa is time in U.T. on February 3, 1966

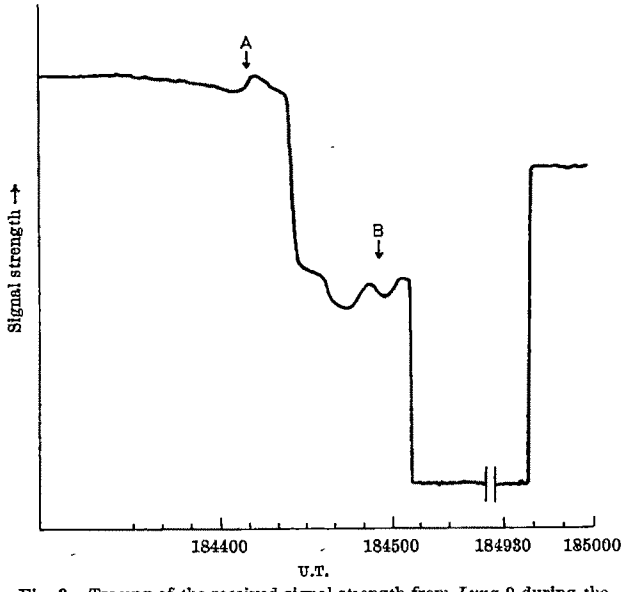

Fig. 3. Tracing of the received signal strength from *Luna* 9 during the landing phase The ordinate is the signal amplitude in arbitrary units (the level at *A* is about 12 dB signal · noise ratio). The abscissa is the time in U.T. on February 3, 1966

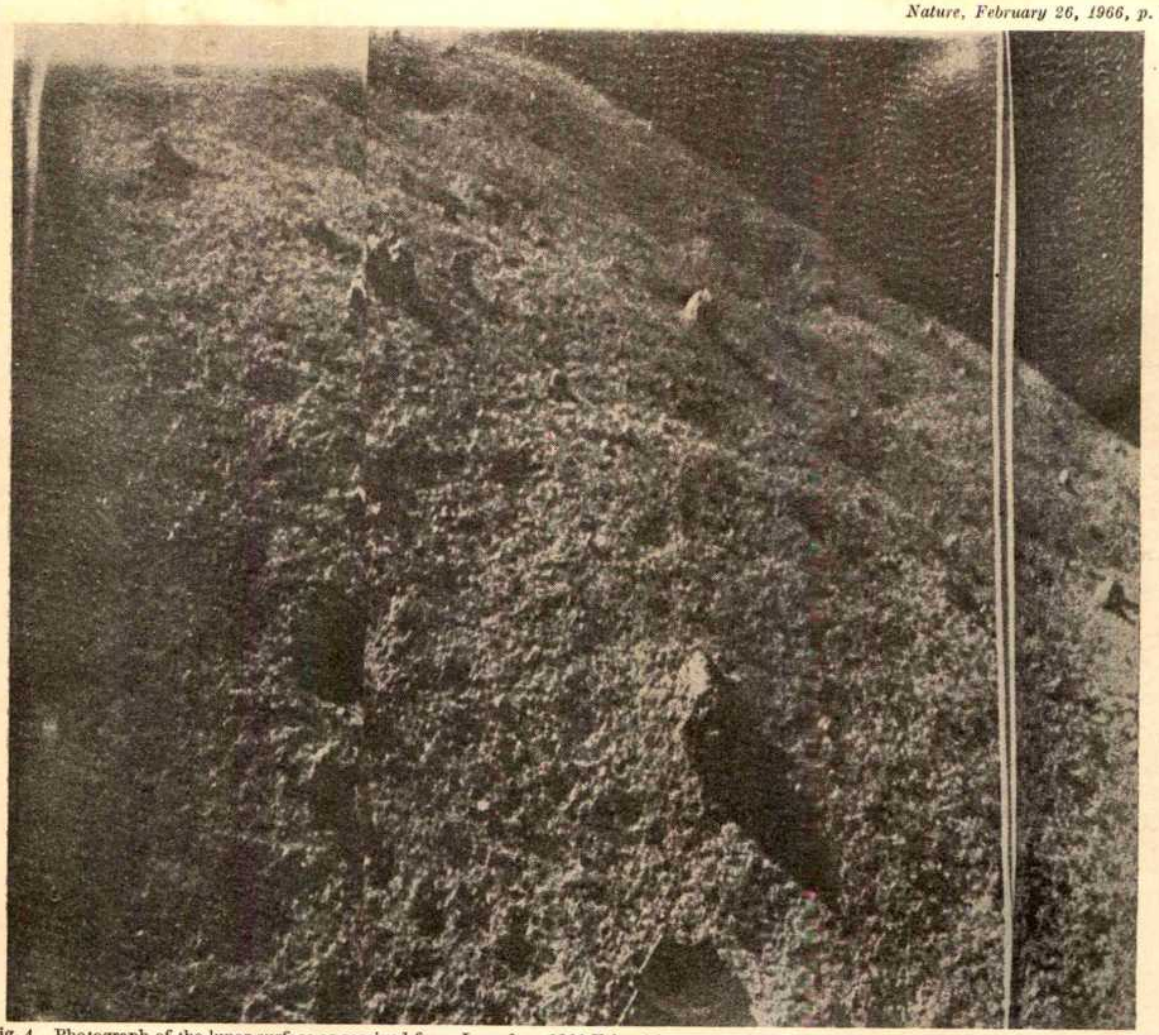

Fig. 4. Photograph of the lunar surface as received from *Luna* 9 on 1966 Febr. 4 between 15h 30m and 16h 55m U.T. A part of the protective fairing of the probe is visible in the foreground. According to information received from the U.S.S.R. the horizontal scale is compressed by 2·5 times

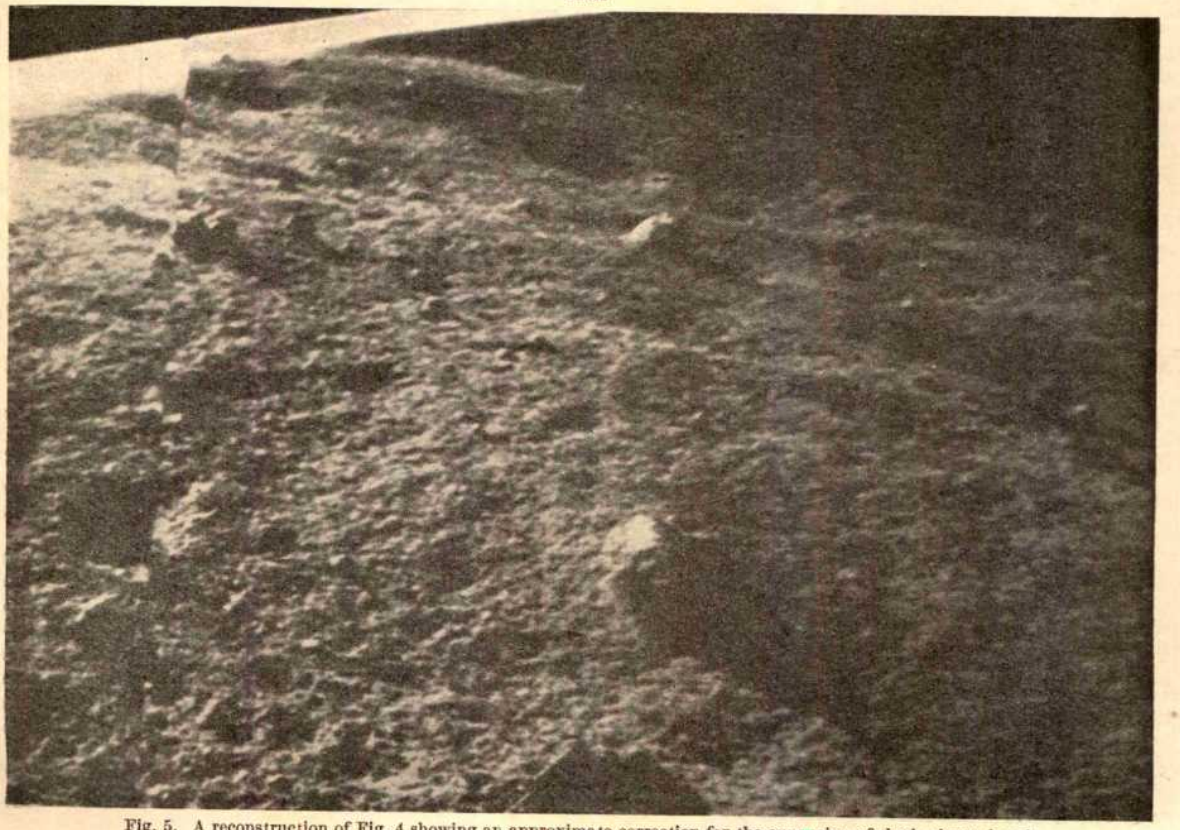

Fig. 5. A reconstruction of Fig. 4 showing an approximate correction for the expansion of the horizontal scale

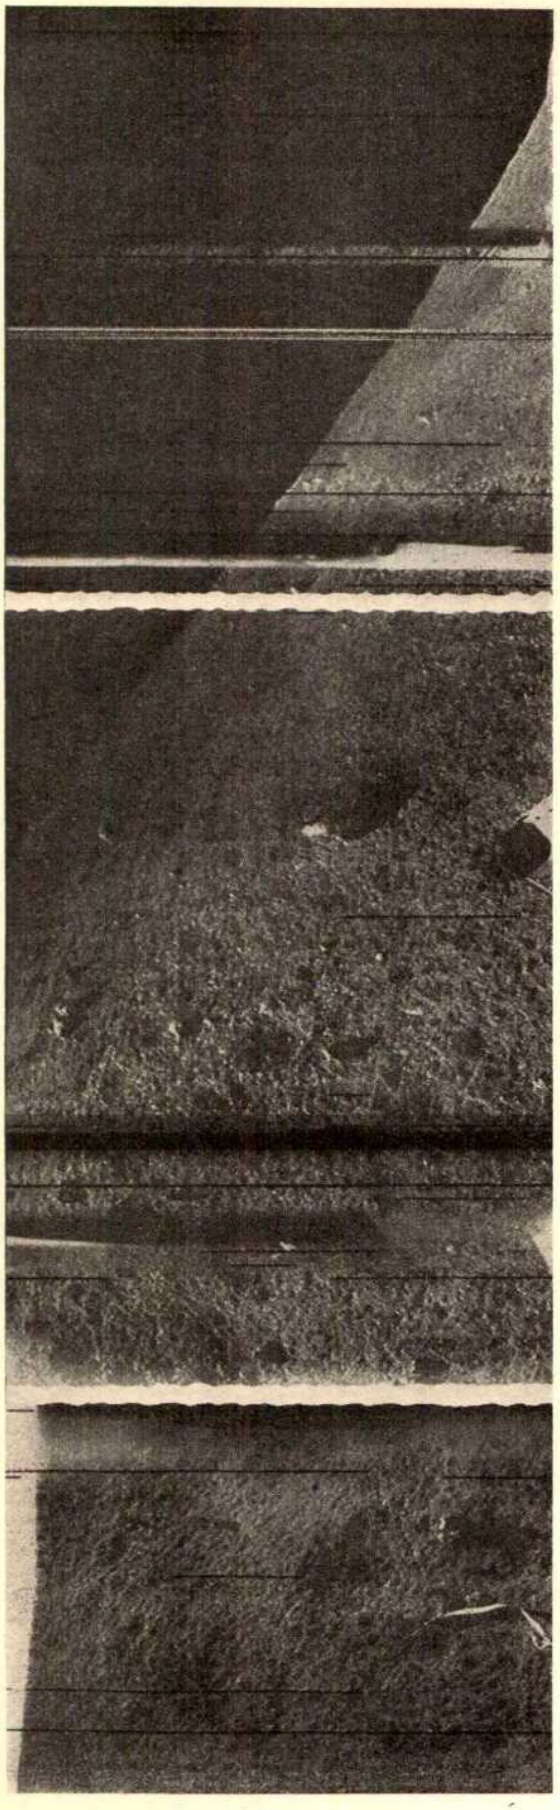

Fig. 6. A reconstruction of a panoramic sequence of the lunar surface as received from *Luna* 9 on 1966 Febr. 5 between 16h 40m U.T. and 17h 40m U.T. According to information received from the U.S.S.R. the horizontal scale is compressed by 2·5 times

and the rate of change of frequency increased from 2 c/s/min to 24 c/s/min. Extrapolating this curve to 18h 44m 30s, the time at which impact would have taken place had the retro-rockets not been fired, the rate of change of frequency at impact would be 25·8 c/s/min, corresponding to an acceleration of 0·705 m/sec². Comparing this with the Moon's surface gravity of 1·62 m/sec², it appears that the landing occurred approximately 64° from the centre of the Moon's visible disk. This compares well with the value of 61° computed from the published landing area and allowing for libration.

The variation of frequency from 18h 44m to 18h 45m is shown in more detail in Fig. 2. Each measured point lies on one of three smooth curves. Up to 18h 44m 08s, the points lie on the curve corresponding to free fall; from 18h 44m 10s to 18h 44m 52s a rapid deceleration occurs, increasing from 32·4 to 76·0 m/sec² over the interval. After 18h 44m 54s, the frequency remained constant within 2 c/s, corresponding to the transmitter being at rest on the Moon's surface. The total frequency change from 18h 44m 08s to 18h 44m 54s is 675 c/s, corresponding to a line of sight velocity of 1,108 m/sec, or total velocity of 2,540 m/sec, or 1·07 times the escape velocity from the lunar surface. Integration of the deceleration curve indicates that the retro-rockets were fired at a height of 68·5 km. Insufficient detail of the moment of landing is available, but it is clear from the shape of the curve that the impact velocity was very low.

The variation of strength of the received signal over the landing phase is shown in Fig. 3. The deceleration commenced at the point marked *A*, and produced no significant change in strength. Approximately 15 sec later the strength decreased over about 1 sec to about a third of the original power. At the point marked *B*, the deceleration ceased, once again without much change in signal strength. Twelve seconds later, at 18h 45m 07s, the signals ceased. During all this time the carrier was modulated with telemetry information.

The Reception of the Photographs

Approximately 4 min after landing at 18h 49m 38s the signal reappeared at precisely the same frequency, with an amplitude somewhat less than the original and with telemetry of a type different from the previous transmissions. At 18h 58m 45s the type of telemetry again changed and the detected phase modulated signal consisted of a variable tone in the range 1·4–2·6 kc/s. This was quickly recognized to be a facsimile transmission with an approximate one-second line scan. This variable tone was fed through a Muirhead Type *D* 665 FM/AM convertor into a Muirhead picture receiver Type *D*-700-*A*. Fig. 4 is an example of one of the photographs received on February 4 during the facsimile transmissions which began at 15h 30m and ceased at 16h 55m U.T. The Russians stated that the horizontal scale of the pictures issued from Jodrell Bank was compressed in the horizontal direction by 2·5 times. An approximate correction of Fig. 4 to allow for this extension is shown in Fig. 5. Fig. 6 is the panoramic view received on February 5 between 16h 40m and 17h 40m U.T. The signal strength during the reception of the facsimile transmissions decreased from 12 dB in an 8 kc/s bandwidth on February 4 to 3 dB on February 6.

The variation in the length of the shadows between February 4 and 5 is clearly visible by comparison of Figs. 4 and 6, and an idea of the scale can be obtained from the appearance of the protective fairing in the foreground of both pictures. For example, the conspicuous stone near the fairing is about 6 in. across and, on the assumption that the camera was 2–3 ft. above the surface, the horizon is 0·5–1 mile distant. Other parts of the probe are visible in Fig. 6.

We thank the editor of the *Daily Express* for his co-operation in lending us the Muirhead convertor and picture receiver.

THE MOON FROM *LUNA* 9

By Dr. G. FIELDER and L. WILSON
University of London Observatory, Mill Hill
AND
J. E. GUEST
Department of Geology, University College, London

THE Russian probe *Luna* 9 was reported to have landed at the selenographic position $\lambda = 64°\ 22'$ W., $\beta = 7°\ 8'$ N. (astronautical convention). This places it 70 km north-east of the rim of the well-known 64-km diameter structure, Cavalerius, on the border of Oceanus Procellarum. The touchdown appears to have been on a bright, slightly elevated area within a few kilometres of a group of hills known, from Earth-based studies, to mark out the arc of a partial ring some 100 km in diameter. When *Luna* 9 landed, this whole region was in darkness; morning broke on the scene about an Earth-day later and picture transmission commenced soon afterwards. As a consequence of the Sun being only a few degrees above the horizon, even small obstacles cast long shadows; contrast was high and detail sized appreciably less than 1 cm was recorded in the near field of each photograph.

Blocks of rock 1 ft. or so in diameter and depressions are not uncommon and, at smaller sizes, the terrain is extremely rough. In the highly successful *Ranger* experiments carried out by the United States, 1 ft. was about the best resolution attained by the last photographs of each series; yet, even at this resolution, positive topography, such as blocks of rocks, was rare and virtually all the easily identifiable topography in the *Ranger* photography was negative. *Rangers* 7, 8 and 9 impacted in mare-type country, and the greater proximity of the touchdown point of *Luna* 9 to lunarite hills may be thought to explain the increased numbers of rock blocks per unit of surface. However, one clear—perhaps the most important—explanation of the difference between the American and Russian pictures is that ground resolution attained by *Luna* 9 is better by two orders of magnitude than that of any of the *Ranger* cameras.

The difference is not simply a function of the respective camera-to-ground distances and the lens characteristics; on the Moon the amount of detail recorded on photographs is critically dependent on the altitude (A) of the Sun and, while the first pictures from *Luna* 9 were taken with $A = 7°$, the later pictures of the three *Ranger* series were taken with $A = \sim 20°$, $\sim 15°$ and $\sim 10°$, respectively.

Thus the terrain would necessarily appear smoother on the *Ranger* photographs. Although some astronomers argued that the *Ranger* programme supported the 'deep-dust' theory, it was known that, in order to satisfy the Moon's peculiar light-scattering properties, the surface must in fact be highly porous. Elementary visual[1], photographic[2] and millimetric[3] observations combined had argued convincingly against an appreciable dust cover. Furthermore, evidence from the *Ranger* photographs themselves has been used[4] to demonstrate that apparent smoothness on the photographs may not be real. We believe that the greater part of the Moon will show a roughness comparable with that shown by *Luna* 9. For the first time there would seem to be complete proof that this part of the Moon does not have an appreciable cover of unsintered dust.

The first pictures from *Luna* 9 reveal a remarkable array of detail down to half a centimetre in size. *A* (Fig. 1) is apparently one of the petal-shaped covers that dropped away from the camera housing after touchdown. *B* is the sunrise shadow of the rock *C*, which itself is very pitted and may be as porous—possibly with a bulk density as low as 0·5 g/c.c.—as the surrounding terrain. It is a rounded rock about 15 cm in diameter, some 2 m from the camera. *D* is a second, rounded rock-block much larger than *C*. We have used two methods to estimate its size. First, the apparent roughness of the terrain between *C* and *D* changes by a factor of 10, so, assuming the average size of irregularities is constant over this distance, unit apparent transverse length at *D* is actually ten times the same unit at *C* and the distance from the camera to *D* is ten times the distance from the camera to *C*, quoted as 2 m. Thus the distance to *D* is about 20 m. This, and a second method based on the fact that the apparent (foreshortened) width of the shadow of *D* is a monotonic function of distance from the camera and the height of the camera above the ground, yield results compatible to within a factor of 2 on the assumption that the terrain is flat: the estimated diameter of block *D* is ~ 1 m. Many other blocks of rock or boulders may be seen in Fig. 1. The closest appear to be rounded and to be buried by only a small fraction of their diameters.

This finding and the observation that the vehicle did not penetrate to any great extent indicate that the surface has an appreciable bearing strength. From calculations based on possible ejecta from a supposed impact crater photographed by *Ranger* 9, G. P. Kuiper[5] estimated a crushing strength of > 1 kg cm^{-2} and this appears to be consistent with what is known of the *Luna* 9 landing vehicle.

It is unlikely that a spherical rock mass is an extrusive or the eroded top of an underlying rock mass. Rather, it appears that the blocks have been deposited on the surface. A cluster of blocks may be seen at *E*. They cannot be meteorites; even at the minimum velocity of 2·4 km sec^{-1} they would have penetrated some distance and scooped out impact craters explosively, breaking up in the process. Furthermore, it is unlikely that the blocks are ejecta from a primary impact crater, since the velocities of the secondary particles would still be of the order of 1 km sec^{-1} and, at these velocities, the blocks would probably break up on impact. Now towards the skyline in Fig. 1 there is a crater-like depression *DA* estimated by us to be of the order of 10 or 20 m in diameter. Could it be that this is a secondary impact crater—either of meteoritic or volcanic origin—and that the blocks were jettisoned as tertiary objects at low velocity? On another picture a similar-sized depression occurs a short distance away. Undoubtedly, these two objects would have been interpreted on *Ranger* photography as depressions without raised rims. Such depressions are generally regarded to be collapse craters. The *Luna* 9 pictures do not show clearly whether the rounded rims of these craters are raised above the surrounding terrain—which is hummocky—or not. If the depressions are due to collapse, then it would seem that the blocks strewn around outside could be volcanic bombs tossed out during mild eruptive phases. A similar distribution of particles can be seen around certain terrestrial volcanic centres[6–8].

There appear to be some sub-parallel features *FF* running across Fig. 1. The fact that there is more than

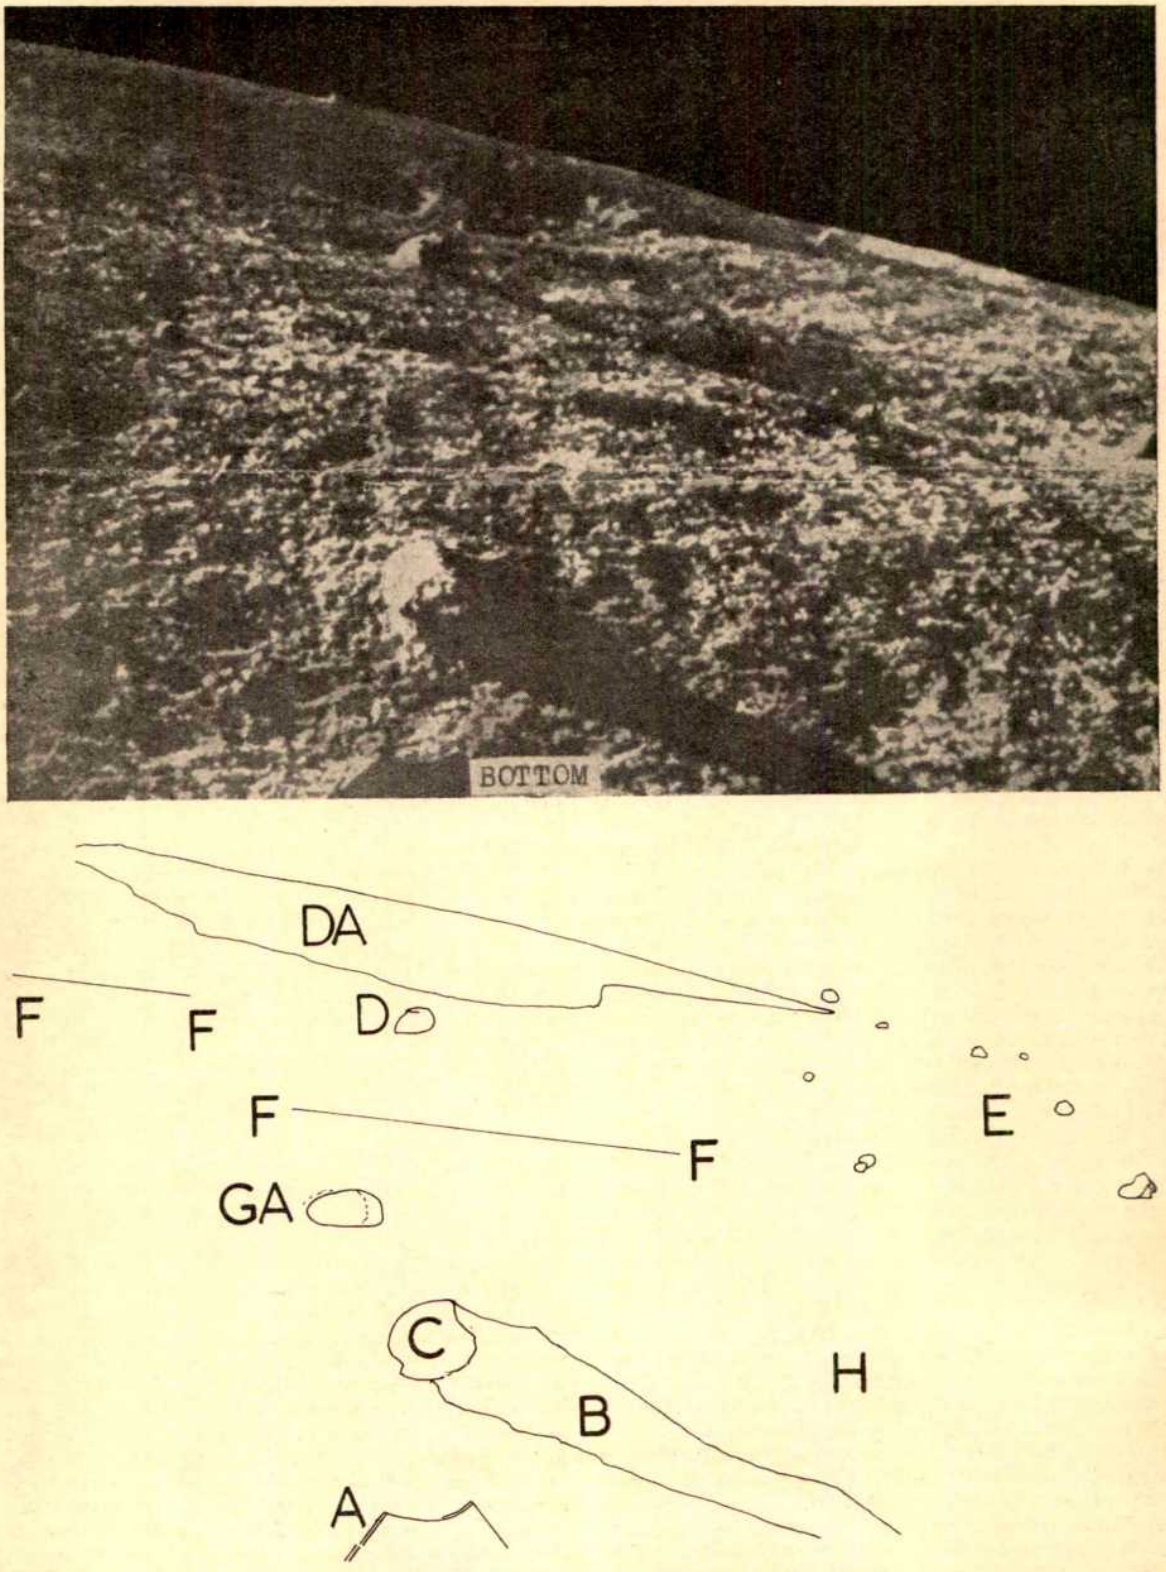

Fig. 1. *Luna* 9 photograph received from the U.S.S.R., February 4, 1966. This shows the closest view yet taken of the lunar surface. (Associated Press picture issued by the Official Soviet News Agency, Tass.) Bottom, key (see text)

one apparent lineament and that the terrain appears to change character across the lineaments suggests that they are real. These markings could be flow lines on, or fronts of, a lava flow; or they could be part of a concentric fracture system related to impact. Because of the similarity of the terrain to a lava terrain we prefer the former interpretation.

The skyline is reported to be only 1·5 km away. It undulates, like all the terrain, gently; slopes on a metre scale being of the order of 4°, excepting those of crater walls such as *GA* which have slopes steeper than 13°. Such craters may be primary or secondary impact craters. Secondary craters may be produced by the throw-out from a primary impact site or they may be produced

when blocks hurled from an explosive volcanic eruption dig into the surface materials.

A whole plethora of steep-sided irregularities are, however, found on the centimetre scale. At this scale (*H* in Fig. 1) the lunar surface bears a remarkable similarity to the scoriaceous surface of an aa (Hawaii) type of lava flow, but we recognize that the irregularities might equally well have been sculptured by meteoritic churning. In any event, solar sputtering must have played a part in shaping the sub-centimetric irregularities and the short-wave and corpuscular radiation from the Sun must, in addition, have darkened the rocks from their original lighter tone.

It is well known that the lunar surface has reflexion properties unlike those of any terrestrial materials. These unusual properties are well illustrated by the graph in Fig. 2. The figure shows the brightness of marial material as a function of angle of observation for a given constant angle of incidence (in this case 30°), and is constructed by reducing the lunation brightness curves of many points to the curve of mean albedo; data have been derived from measurements by Fedoretz[9] and Bennett[10]. It seems that the observation that the Moon's surface (in both maria and highland areas) scatters a large fraction of the incident light back in the direction of incidence can only be explained satisfactorily by assuming that the surface is very rough and, in particular, that individual holes or pores are interconnected.

We have attempted to explain these features on the assumption that at least some parts of the lunar surface consist of lava flows. If this is so it will be appreciated that the lava reaching the surface encounters not an atmosphere as in the case of the Earth, but a high vacuum, and as a result any release of entrapped gas is likely to cause a higher degree of vesicularity than in the corresponding terrestrial case. Following Dobar *et al.*[11], we have, therefore, rapidly evacuated the atmosphere from vessels containing molten igneous rocks and examined the resulting solids after cooling to room temperature. In all cases a highly vesicular material is found consisting of interconnected vesicles from 0·1 to 2 or 3 cm in diameter. Such material, when darkened by solar radiation, is consistent in appearance with the terrain so far resolved in the Russian photographs, and our material also reproduces the observed lunar photometric properties. It is

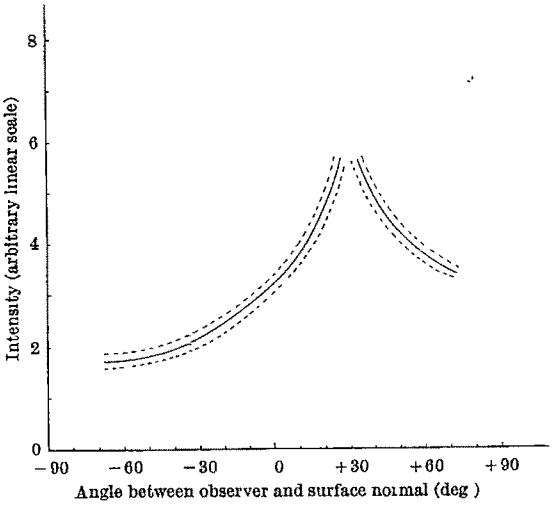

Fig 2 Scattering diagram for maria with angle of incidence of sunlight =30 degrees The dashed lines indicate the limits of probable error

not yet possible to decide to what extent the surface has been broken up by meteoritic impacts and re-sintered by the solar bombardment; photographs taken with a resolution of less than 1 mm will be needed to resolve such questions. There is, however, strong evidence based on polarimetric observations[12] that the irregularities photographed by *Luna* 9 will be found to be peppered with darkened but individual grains that are certainly produced by micrometeorites.

Part of this work was supported by a research grant from the Science Research Council.

OBITUARIES

Sir Gordon Morgan Holmes, C.M.G., C.B.E., F.R.S.

Sir Gordon Morgan Holmes died at his home in Farnham, Surrey, on December 29, 1965. He was in his ninetieth year.

Holmes was born in Castlebellingham, Co. Louth, Ireland, in 1876. After gaining his M.D. with the gold medal of the year from Trinity College, Dublin, he was for a short period a resident medical officer at the Richmond Hospital in Dublin, but then turned to the study of the comparative anatomy of the nervous system and proceeded to the Anatomical Institute at Frankfurt, then directed by the famous neuro-anatomist, Ludwig Edinger, where Holmes also encountered another pioneer in the field, Carl Weigert.

During the two years that he remained at Frankfurt he produced work on the nervus acusticus, on the forebrain of the bird, and was given by Edinger the task of working out the residual anatomy of one of Goltz's 'dogs without forebrain'. So impressed was Edinger by his young student that he offered Holmes a position as his assistant, and this might well have determined Holmes's future place and order of study. However, he came to England and turned to neurological medicine, filling successively the roles of resident medical officer, pathologist, director of research and finally physician to the National Hospital, Queen Square, London, until his retirement during the Second World War.

From his first arrival at this well-known neurological hospital, which enjoyed an international reputation for research many years before it finally achieved university recognition after Holmes's retirement, his output of original work was continuous. It covered the anatomical and morbid anatomical investigation of the human nervous system and the manifestations of diseases of the nervous system over a wide range.

The study and analysis of cerebellar defect, due to disease or injury, began in 1904 when, with Grainger Stewart, he published the first adequate study of cerebellar tumours. Later, during the First World War, which he spent in France as neurological consultant to the British Forces, he amplified his analysis of cerebellar function by investigations on acute injuries from gunshot wounds. The final results of all his investigations on this subject were published in 1917 and 1922.

During the opening decade of the century he worked in collaboration with Henry Head on disturbances of sensation associated with cerebral lesions, drawing from them inferences as to the role of the cerebral cortex in sensory function.

This was a remarkable collaboration, for Holmes, his training soundly anchored in anatomy, not only devised quantitative methods of sensory assessment, but also was a brake on Head's eager fancy. It will be remembered that Head's early studies with Rivers on the afferent sensory system, though brilliant, had a fatal defect, in that Nature had not provided the structural facilities for the theories which they had put forward. Holmes, therefore, was an essential complement to his partner in this work, and between them they produced a more delicate and precise concept of the role of the cortex in sensation than any earlier one.

Also during the period spent in France, Holmes made a number of valuable studies on disturbances of visual function from brain lesions. These included a somatopic cortical representation of the afferent visual pathway, and the bases of visual orientation and attention. These considerable cerebellar and visual studies were collected and published as a supplement to *Brain* (of which journal Holmes was editor during 1922–37) in 1956 on his eightieth birthday. Appended to that supplement is a bibliography of his published work which reveals his immense productivity and the wide range of his thought over the fields of neurological anatomy, physiology, morbid anatomy and nosography.

During the years between 1919 and 1939 Holmes also gained an international reputation as an incomparable teacher of postgraduate students in neurological medicine. These young men flocked to the National Hospital from the British Commonwealth and from the United States to join Holmes's staff as clinical clerks. These clerks and his own house physicians formed a generation of neurologists still to be found in all parts of the English-speaking world, holding senior positions in neurological departments. Holmes was an exacting taskmaster to these men, but he had the gift of lucid and logical exposition so that the 'how' and 'why' of his conclusions and of his diagnoses were apparent. He was not a showman anxious to impress, but a born teacher.

Personally, Holmes was a man of great strength and inexhaustible energy and of a forceful temperament, sometimes frightening but never malicious, always gaining the respect and later the affection of those he taught. To be trained by him was a salutary discipline. Committees he loathed, and was an impatient and sometimes intolerant member of them. But for younger men in whom he saw a keenness and a capacity for original work he had infinite patience and sympathy.

Finally, it is worthy of note that Holmes was one of the last representatives of those physicians of an earlier generation who depended entirely on the private practice of consulting medicine, whose research was carried out in their hard-won spare time, and who wholly lacked academic or other support. With the death of the voluntary hospitals this way of life ceased to be.

Holmes was appointed C.M.G. and C.B.E. during the First World War and was knighted in 1951. He was elected a Fellow of the Royal Society in 1935; he was an honorary member of numerous foreign medical societies, and received honorary degrees from the Universities of Dublin, Durham and Edinburgh and from the National University of Ireland. He married, in 1918, Rosalie, daughter of Brigade-Surgeon Jobson, and had three daughters.

F. M. R. Walshe

Prof. William Wilson, F.R.S.

William Wilson died on October 14, 1965, at the age of 90. He retired in 1944 from the Hildred Carlile chair of physics at Bedford College, University of London, which he held from the time of its creation in 1921. He came from a farming family and spent his boyhood at Goody Hills in Cumberland. From the village school at Holme St. Cuthbert he obtained scholarships to the Aspatria Agricultural College and to the Royal College of Science. At this stage, he found difficulty in changing his course of study from one in biological subjects and temporarily abandoned his scientific career for school teaching. He taught English in the Berlitz School of Languages in Dortmund for a time, but was able to return to scientific work by studying physics and mathematics in German universities. Later in life he often praised the freedom of choice which was given to students in Germany and held that the British system of examinations imposed an undesirable and discouraging rigidity.

His first published work, in the *Annalen der Physik* for 1907, is an extract from his Dr. Phil., Leipzig, inaugural dissertation. It is an account of experiments on photoelectric emission and on the photoconductivity of such materials as silver iodide. He long retained an interest in the photoelectric effect and published a quantal theory of thermionic emission based on the idea that the electrons were ejected photoelectrically by quanta of radiation in thermal equilibrium. He showed that the temperature dependence would be similar to that deduced by O. W. Richardson, who used non-quantal arguments. It later became clear that these photoelectrons could account for only a small fraction of the thermionic current.

After becoming an assistant lecturer at King's College, London, in 1906, his interest was aroused by the atomic speculations on nebulium of Prof. J. W. Nicholson, professor of mathematics at the College, which antedated Bohr's theory of the hydrogen spectrum. In 1915 Wilson's famous paper "The Quantum Theory of Radiation and Line Spectra" appeared in the *Philosophical Magazine*. In this he first proposed the Wilson–Sommerfeld quantization rules in the form:

$$\int p_1 \, dq_1 = \rho h$$
$$\int p_2 \, dq_2 = \sigma h$$
$$\int p_3 \, dq_3 = \tau h$$

where $\rho, \sigma, \tau, \ldots$ are positive integers (including zero) and the integrations are extended over the values p_s and q_s corresponding to the period $1/\nu_s$. The q are Hamiltonian generalized co-ordinates of position and the p are their conjugate components of generalized momentum. The paper applied the rules to the simple harmonic oscillator, to find $E_\rho = \rho h\nu$. An application of statistical mechanics to an assembly of oscillators gave Planck's radiation formula but failed to give the Bohr frequency relation:

$$h\nu = E_1 - E_2$$

In 1916 appeared "The Quantum of Action", which preceded Sommerfeld's first paper on the subject. In this Wilson deduced that if elliptic orbits existed in the atom they could only have a few discrete values of the eccentricity ε given by

$$\sqrt{1-\varepsilon^2} = \sigma/(\rho+\sigma)$$

where σ and ρ are positive integers as before.

Wilson did not follow this up, but in the quite independent work of Sommerfeld on the other side of the firing lines in Germany it led to the idea of space quantization and to a theory of the fine structure of the lines of hydrogen. In this theory the energies of the levels agreed with the values given later by the relativistic wave mechanics of Dirac.

The sharply defined elliptic orbits used in the theory are incompatible with the indeterminacy relations of Heisenberg, so that their success in explaining the fine structure must be regarded as an accidental coincidence. In this, the theory resembles many other steps forward in

the history of quantum mechanics in which nearly every advance has been shown later to have contained some erroneous components.

Wilson's later work was mainly concerned with basic problems such as a search for a relation between general relativity, electromagnetism and quantum mechanics. In the final volume of his text-book *Theoretical Physics*, which appeared in 1940, he expressed the view that a unified theory may follow the ideas of Kaluza who, in 1925, suggested that the paths of particles were geodesics in a 5-dimensional continuum. The fifth dimension would be related to the conservation of charge.

In all his researches he chose difficult subjects which were insoluble with the state of knowledge at the time. In his last years he was engaged in speculations concerning the shapes of the spiral nebulae.

Wilson was a fluent and remarkable lecturer and teacher. He had an unusual gift for personal contact and discussion with each student, often during the course of a laboratory class. His *Theoretical Physics*, in three volumes, contains many short, clear and original derivations of formulae. After his retirement he published the *Microphysical World* and *A Hundred Years of Physics*.

The latter contains valuable details of the history of recent ideas of the structure of the material world. It is at the same time an excellent, concise text-book of modern physics in which the human interest of the story helps the reader to follow the subtle arguments and experiments by which the facts have been established. The book is one of the "Hundred Years" series, but the title has perhaps deterred undergraduate students from appreciating its virtues as a source of information.

Wilson's wife died in 1957. He is survived by his son and his grandchildren. H. O. W. RICHARDSON

Dr. Basil Roland Record

DR. B. R. RECORD, senior principal scientific officer in the Ministry of Defence, head of the Biophysics Section of the Microbiological Research Establishment, Porton, died at his home in the New Forest on November 17, 1965. He was fifty-four years of age.

He was educated at King Edward School, Birmingham, and as a schoolboy, passionately interested in chemistry, carried out quite advanced chemical preparations in his garden-shed laboratory. With this interest he went on, naturally, to study chemistry at the University of Birmingham under the late Sir Norman Haworth and graduated with first-class honours in 1933. His first research study, also carried out at Birmingham, under the direction of Dr. S. R. Carter, was in the field of physical chemistry—an investigation of the molecular weights of polysaccharide derivatives using osmotic pressure methods. The osmometer designed by Carter and Record for use with organic solvents formed, then, a notable advance in technique and is still quoted approvingly in modern texts.

In 1937, with the aid of an extended scholarship from the Department of Scientific and Industrial Research and with Sir Norman's encouragement, he was one of the earliest of those who went to work in Prof. Svedberg's laboratory in Uppsala to use the ultra-centrifugal and diffusion techniques then recently developed there. He found the 18 months he spent in Sweden in the quiet university town of Uppsala among the happiest of his working days, and it was there that he produced his very successful results on the physico-chemical characteristics of a series of methylated glycogens and of the specific polysaccharides from Types I, II and III pneumococcus. Although the publication of this work was much delayed, the observations must have been the earliest demonstration of the strong dependence of sedimentation and diffusion coefficients on concentration found with some materials.

Although he thought seriously of remaining longer in Sweden, where he found the way of life much to his liking, the prospect of approaching war sent him back to England in 1938 to join Drs. A. S. McFarlane and R. A. Kekwick, who had by then brought both a Svedberg ultra-centrifuge and Tiselius electrophoresis apparatus into operation at the Lister Institute. It is in striking contrast with present-day science that in his first year at the Lister Institute no financial support could be found for him from either the Lister or public funds. In 1939, however, he was awarded a coveted Beit Memorial Fellowship, which he held until he resigned it in 1940 to undertake more active war work. It was during this period at the Lister that he worked with R. A. Kekwick on a physico-chemical investigation of the development of diphtheria anti-toxin in the immunized horse and the characteristics of anti-toxin proteins, the work which he, in retrospect, thought of as his most successful.

From 1941 until 1944 he worked in the Army Operational Research Group under Brig. Schonland, and principally on radar predictors, field fire-control procedures (anti-aircraft) and trials of new equipment. It was typical of him that, conceiving that he could not work freely and scientifically under senior army officers, he refused throughout to accept a commission though at much cost to himself in terms of income and the advantages of commissioned rank in war-time.

In 1944 he was released from the A.O.R.G. at the request of Sir Alan Drury to join the 'Medical Research Council–Lister Blood Products Unit' which had been set up at the Lister Institute to undertake human plasma fractionation and, initially, the preparation of fibrinogen and thrombin which, together with fibrin foam, were urgently required for war-time clinical application: at a later stage the work was extended to cover the production of γ-globulin and albumin. He had a marked aptitude, and took much pleasure in his engineering skills and contributed to the design of pilot plant equipment for plasma fractionation under aseptic conditions.

The final move in his career was made in 1947 when, at the urgent request of the director, Dr. D. W. Henderson, he took up an appointment at the Microbiological Research Establishment. Here he was made responsible for the formation of a biophysics unit together with an extensive freeze-drying laboratory, for which he designed a range of freeze-drying machinery. Under his guidance, physico-chemical investigations of several biologically important macromolecular systems were made, including, particularly, botulinus toxin and polyglutamic acid, the latter of interest both biologically and as a member of the then emerging field of polyelectrolyte systems. He was, however, most particularly concerned with the fundamental aspects of the survival of micro-organisms during the freeze-drying process.

His work was characterized by the most scrupulous attention to the conception, design, performance and analysis of experiment, by his insistence that deductions and conclusions were adequately based on experiment and by the preparation of careful, clearly written and unambiguous reports: nothing aroused his anger more than the inclusion of unwarranted speculation in a scientific paper. Although somewhat retiring, he had a strong personality, and he was devoted to the idea, perhaps no longer really possible, that a scientist should be personally engaged in experimental observation and, in consequence, showed no desire to form a large group of workers, but gathered and retained only a few bound to him by his integrity and friendship.

Conflicting with his laboratory-bound science was his wish to be actively engaged outdoors, and he was fortunate in having spent his last years in a house with a large woodland garden in the New Forest, which gave him the greatest pleasure. R. G. WALLIS

NEWS and VIEWS

The Royal Society: Vice-Presidents

The president of the Royal Society, Prof. P. M. S. Blackett, has appointed the following vice-presidents for the year ending November 30, 1966 (in addition to those already announced in *Nature*, 209, 134; 1966): Dr. S. G. Hooker, technical director (aero), Bristol Siddeley Engines, Ltd.; Dr. R. D. Keynes, director of the Institute of Animal Physiology, Babraham, Cambridge; Sir Hans Krebs, Whitley professor of biochemistry at the University of Oxford; Dr. N. Kurti, reader in physics, University of Oxford, and Senior Research Fellow, Brasenose College.

Director of the Radio and Space Research Station: Mr. J. A. Ratcliffe, C.B., C.B.E., F.R.S.

Mr. J. A. Ratcliffe retires on February 28 from the directorship of the Radio and Space Research Station of the Science Research Council. He went to this post from the Cavendish Laboratory, Cambridge, in 1960. Educated at Giggleswick School, Mr. Ratcliffe proceeded to Sidney Sussex College, Cambridge, where he graduated in physics in 1924. He began research under E. V. Appleton at the time when he was making the important experiments which established the existence of the ionosphere, and it was Mr. Ratcliffe's collaboration in this work which first stimulated his enthusiasm for the subject which has since been his main scientific interest. He was appointed a demonstrator at the Cavendish Laboratory in 1927, and it was also during this pre-war period that he acquired his high reputation as a teacher of physics. After service in radar research and development during the Second World War, for which he was appointed an O.B.E. in 1947, he returned to Cambridge and resumed work at the Cavendish Laboratory, where he became a reader in physics in 1947. The reputation he had acquired as a teacher and research worker attracted many young graduates to his radio research group and it quickly acquired a high international reputation. A firm believer in the importance of international co-operation in science, Mr. Ratcliffe has played a prominent part in the work of the International Union for Scientific Radio, of which he is, at present, chairman of Commission III (Ionospheric Research). He served as an overseas vice-president of the Institute of Radio Engineers of America in 1960. He was president of the Physical Society during 1958–60 and is at present senior vice-president of the Institution of Electrical Engineers. The Institution has just announced the award to him of the Faraday Medal for 1966, in recognition of his "extensive researches on the ionosphere, and for his studies on the propagation of low frequency radio waves". Mr. Ratcliffe was appointed C.B.E. in 1959 and C.B. in 1965. He became a Fellow of the Royal Society in 1951. His College, Sidney Sussex, made him a Fellow in 1927 and an honorary Fellow in 1965.

Dr. J. Saxton

Dr. John Saxton has been appointed director of the Radio and Space Research Station, Ditton Park, Slough, Bucks, in succession to Mr. J. A. Ratcliffe. Dr. Saxton is director of the United Kingdom Scientific Mission in Washington, D.C., and Counsellor (Scientific) at the British Embassy there. Before taking up this appointment he was deputy director of the Radio Research Station. Educated at Loughborough Grammar School and the Imperial College of Science and Technology, London, Dr. Saxton joined the staff of the College after graduation and carried out research on artificial radioactivity before joining the Radio Division of the National Physical Laboratory in 1938. (This developed into the Radio Research Station in the early 1950's.) Dr. Saxton's work on the dielectric properties of the atmosphere and on studies of the propagation of radio waves at very high frequencies have made him well known in Europe and North America. In 1961, at the invitation of the University of Texas, he spent a year there as visiting professor of electrical engineering.

Master of Birkbeck College: Prof. F. K. Hare

Prof. F. Kenneth Hare, professor of geography at King's College, London, has been appointed master of Birkbeck College, in succession to the late Sir John Lockwood. Prof. Hare was born on February 9, 1919, and graduated B.Sc. (special) in geography at King's College in 1939 at the early age of twenty. He had already started research on land use in Galloway and on geochronology in the Thames Valley, combined with graduate work in meteorology. During the Second World War he was one of the small band of scientists behind the plans for the Normandy landings, where such difficult but vital problems as the relation between weather, soil, mud and tank-performance had to be considered. Moving to Canada as assistant professor at McGill University, Hare soon succeeded to the headship of the Department of Geography, and became involved in such diverse activities as establishing research stations in Labrador and Barbados and the air survey of the Northlands. A doctorate from the French-speaking Université de Montréal, a deanship at McGill, an Hon. LL.D. from Queen's University and election as honorary president (being a non-American) of the Association of American Geographers mark stages in North American appreciation of his work. Tempted back to England in 1963 to succeed his old chief, the late Prof. S. W. Wooldridge, Hare has been playing an active part in both the Natural Resources Advisory Committee and the Natural Environment Research Council.

United Kingdom Atomic Energy Authority: Prototype Fast Reactor

In a statement in the House of Commons on February 9, the Minister of Technology, Mr. F. Cousins, said that the Atomic Energy Authority had advised him that the design of a prototype fast reactor was sufficiently advanced to justify starting construction and this had been sanctioned by the Government. The prototype would generate 250 MW and, with the associated fuel production plant, would cost about £30 million. It was expected that the reactor would come into operation in 1971. The Atomic Energy Authority had advised him that only the reactor development establishments at Dounreay and Winfrith would be suitable sites from the technical point of view, and after considering all the relevant factors the Government had decided that it should be built at Dounreay. The fuel production plant would be sited at Windscale. A similar statement was made in the House of Lords, also on February 9, by Lord Snow, who in reply to questions added that while Chapel Cross and Windscale had also been considered, only Dounreay and Winfrith merited serious consideration from the point of view of research and development facilities, although social factors had also been taken into consideration.

Channel Tunnel

In a debate in the House of Commons on February 9, Mr. S. Swingler, Joint Parliamentary Secretary to the Ministry of Transport, stated that the preliminary geo-

logical and geophysical studies for the Channel Tunnel had proved very difficult and complicated. The surveys included the sinking of 73 boreholes, land borings, measurements of current, and weather studies. They were put in hand in agreement with the French Government following the Minister's statement on February 6, 1964, in an endeavour to find the best route for either a bored tunnel or a submerged tube. Besides the marine borings, site work completed last October, costing £2·1 million to be shared between the two Governments, had included several hundred miles of geophysical survey, ten land borings in England, nine land borings in France, measurements of currents and tides in the Channel, many varieties of new tests in the boreholes, and laboratory tests on samples of rocks. For the marine borings, two special platforms and four drilling vessels were used as well as many support ships, and besides five firms of consulting engineers, specialists in geophysics and palaeontology were engaged under the general direction of the Channel Study Group. A supplementary estimate of £845,000 represented the British share of the additional costs due to particularly difficult weather conditions, etc. A report on the survey was expected in March, and the report was likely to show the feasibility of the project. Discussions had also been proceeding between officials of the two Governments on the organization and finance of future stages of a Channel Tunnel project and how the juridical problems involved might be solved.

Concord Project

A FURTHER short debate on the aircraft industry in the House of Commons on February 9, in which Mr. R. Carr again emphasized the critical importance of deciding the stage at which decisions on a highly technical project should be firm, was concerned essentially with the *Concord* project. In replying on the debate, the Parliamentary Secretary to the Ministry of Aviation, Mr. J. Stoneham, said that there had been a slight increase in cost since the estimates were last presented to the House and the specification had been modified from 118 to about 130 seats. The estimates had also been revised by a new system providing a more accurate appreciation of the costs involved, and the assessment, which was being made the part-certificate of airworthiness, would also include considerable costs. There would be a ground test programme of unprecedented scope, including airframe testing with the research facilities at Farnborough. There had been no technical delay, nor any increase in cost resulting from the review of the project, October 1964–January 1965. Much work had been done on the noise factor and the first prototype should be flying early in 1968.

Royal Society Expedition to Tristan da Cunha

THE volcanic eruption that began on Tristan da Cunha in October 1961 and led to the temporary evacuation of the whole population, though not of the domestic animals and birds, was soon followed up by the Royal Society's Expedition in the early months of 1962. Geological and biological reports on this reconnaissance have been published separately. The latter includes the terrestrial botany of the whole island group (Tristan, Nightingale, Inaccessible, also Gough Island) by N. M. Wace and J. H. Dickson; the fauna by M. W. Holdgate; the effects of the eruption on the vegetation of Tristan by J. H. Dickson; and on the fauna by D. E. Baird (*Phil. Trans. R. Soc.*, Series B: Biological Sciences. No. 759, 249 (October 7, 1965). Pp. 257–434+plates 32–47. London: The Royal Society, 1965. 85*s.*; 12.75 dollars). The monograph brings together most of the previous information from other expeditions, with a well-documented analysis of the status of the plant and animal species, both native and introduced by man. Tristan has already more than twice as many invading species of flowering plants as native ones, though they are still largely segregated. The plant communities are described. The faunal analysis is much less complete, but it also shows that there are more introduced species of invertebrates, such as worms, myriapods and beetles, than native ones. Direct damage to vegetation by lava flow and ash was much less than that from toxic fumes which affected a broad zone on the north and north-east sides of the island. The abandoned domestic stock were severely attacked by feral dogs, but the unusual conditions apparently have not severely affected native birds.

The Alaskan Earthquake of March 1964

ON the afternoon of Good Friday, March 27, 1964, Southern Alaska was struck by perhaps the strongest earthquake to have hit North America within historic times, the epicentre being about 80 miles east-south-east of Anchorage, the largest city of Alaska, which suffered damage estimated at about 300 million dollars. Anchorage normally houses a rather large contingent of geologists; and within two days of the earthquake a committee of these local earth scientists, the membership of which rose to forty, was empowered to outline "the necessary and immediate courses of action" to be taken by the city. The group contracted for aerial photography, a drilling programme, soil testing, and geological mapping, producing a preliminary appraisal within two weeks and a final report a month later. Probably no major earthquake has been so thoroughly investigated so soon after its incidence. Contemporaneously, the United States Geological Survey initiated a programme of longer-term investigations, and from the first of its reports to be published it seems likely that this shock will ultimately be more fully documented than any comparable catastrophe (United States Department of the Interior: Geological Survey. Professional Paper 542-A: *Effects of the Earthquake of March 27, 1964, at Anchorage, Alaska.* By Wallace R. Hansen. Pp. iv+68+plates 1 and 2. Washington, D.C.: Government Printing Office, 1965). Damage at Anchorage was caused by direct seismic vibration, by ground cracks, and by landslides, the latter moving on nearly horizontal slip surfaces related to zones of low shear strength and high water content in a glacial clay underlying much of the area. Old landslides predating the settlement of Anchorage and presumably triggered off by earthquakes have now been widely recognized in the vicinity. This first monograph in a continuing series is extensively illustrated and it forms an important addition to the basic literature of engineering geology.

Electrolytic Hydrodimerization

A SCIENTIFIC and technological breakthrough into a new field of electro-organic chemistry has recently been proclaimed by the Central Research Department of the Monsanto Company, St. Louis, Missouri, of which a brief account is given in *Monsanto Magazine* (Monsanto Company, St. Louis, Missouri. 45, No. 5, December, 1965). It is a fascinating story of tantalizing and frustrating research which appears to have been initiated some years ago by Soviet scientists, but their process was not economically feasible. The problem, put into simplest terms, was to convert a plentiful and relatively inexpensive compound, acrylonitrile, into a vital intermediate in the manufacture of nylon; in fact, the compound adiponitrile. The basic argument was that theoretically two molecules of acrylonitrile, if placed end to end and supplied with one more hydrogen atom apiece, would structurally form one molecule of adiponitrile, but hitherto research experiments had failed to discover a *modus operandi* for economically 'splicing' the two acrylonitrile molecules and at the same time adding the necessary hydrogen to complete the adiponitrile structure. This process, as now realized successfully, is an example of hydrodimerization. In the present case the chain of events was started by Dr.

C. A. Hochwalt, Monsanto research and technology vice-president (since retired), who studied the Russian reports. He formed the opinion that some phases of the Russian experiments were of technical interest and were worth following up by Monsanto scientists. It was Dr. M. M. Baizer of the Central Research Department who was critically concerned with one aspect of the Russian approach to the problem, that involving electrolytic reactions; Dr. Baizer disagreed with widely accepted interpretations of the effect of an electric current on organic chemicals, in particular the alleged existence and functions of intermediate fragments, the 'free radicles'; he was convinced that these had been overrated, and were probably not involved at all in the main problem. Dr. Baizer accordingly set to work, on comparatively modest laboratory equipment centring on an electrolytic cell, to see whether his ideas were correct or otherwise. "In a few months, he was ready to report that it did appear, indeed, that free radicles did not necessarily figure in the results. In addition, he was able to report a breakthrough into a new field of electro-organic chemistry. It was the direct electrolytic hydrodimerization of a broad variety of petrochemicals into others twice their molecular size." Later, his process was the basis for many patents, in one case ten being issued on the same day. The mechanism of the process involved is shown diagrammatically in colour in the article and may, in summary, be conveyed as follows: the sequence begins as two acrylonitrile molecules in an electrolyte-water solution are drawn together when current from a cathode breaks the carbon double bond in the first, 'charging' it, causing the carbon double bond in the second to break as the two molecules join ('carbanion'); at this stage two hydrogen atoms from the water are attracted, thus the adiponitrile molecule is formed. Within two years of this discovery, a multi-million-dollar Monsanto plant, with batteries of electrolytic cells many times larger than the original cell used by Dr. Baizer, is busily and efficiently converting acrylonitrile into adiponitrile at Decatur, Alabama; this was described as a technological feat for which, in 1965, Monsanto won one of the most prized honours in this field in America, the Kirkpatrick Award for Chemical Engineering Achievement.

Morphological Analysis by Digital Computer

A COMPUTER-ORIENTED approach to the analysis of microscopic images has been developed by M. L. Mendelsohn, W. A. Kolman, B. Pery and J. M. S. Prewitt, of the Department of Radiology, University of Pennsylvania, around *CYDAC*, a data conversion system which scans through the microscope and records the optical information in digital form on magnetic tape (*Methodik der Information in der Medizin*, 4, No. 4; December 1965). The quality of the optical information thus made available to the computer is surprisingly good, as shown by the reconstruction of the original image using the high-speed printer. Preparations for the computer interpretation of scanned images are under way, using blood cells as a model system. Parallel attempts to classify human chromosomes by means of *CYDAC* scans have given encouraging preliminary results.

Developments in Pure Chemicals

AT present the research and development programme of the B.D.H. Laboratory Chemicals Division is aimed mainly at the production of highly purified inorganic compounds used for optical purposes—principally the hot-pressing of infra-red windows and the growing of crystals for a variety of purposes. The emphasis is always on greater and greater purity since optical properties are profoundly influenced by small traces of some impurities. Associated with this programme is the preparation of highly pure acids and solvents; these are used primarily by the electronics industry for the etching and cleaning of semiconductor surfaces, but they also have an obvious appeal to analysts and those concerned with the preparation of very pure materials. In the past 5 years the company has been engaged in a major effort to make the United Kingdom less dependent on imported biochemicals. Apart from producing many materials formerly available only from the United States, the Biochemical Department has made its own contribution to the range of biochemicals available commercially. Examples include (*a*) a B.D.H. preparation for the world market of the reagent dansyl chloride and a series of dansyl derivatives of amino-acids which are important in protein research; (*b*) the commercial production of high quality ε-(2 : 4-dinitrophenyl)-L-lysine hydrochloride which is important in determining lysine in foodstuffs, especially in milk. It has been important to lipid chemists in Britain that the company has provided reasonably priced methyl esters of very pure higher fatty acids. B.D.H. is playing a large part in the supply of reagents to hospital laboratories. The bacteriologist has benefited from a mucous digestant, *N*-acetyl-L-cysteine; some tetrazolium salts of exceptional quality are speeding the work of the histologist and cytologist (also of those concerned with seed viability testing). Special attention is being paid to the demands of automatic analysis in clinical laboratories by providing ready-made solutions and convenient forms of other reagents.

The Cape Asbestos Company, Ltd.

THE Cape Asbestos Company, Ltd., is the parent company of the Cape Asbestos Group, an international organization with widespread industrial ramifications. The Mines Division includes Cape Asbestos South Africa (Pty.), Ltd., the South African parent company, and affiliated firms, operating amosite mines at Penge, Weltevreden, Kromellenboog and Malipsdrift, blue asbestos mines at Koegas, Westerberg, Pomfret and Warrendale; also the London-based Cape Asbestos Fibres, Ltd., concerned with the promotion, sale and distribution of raw and processed asbestos fibres. The Insulation Division is concerned with various proprietary insulating materials, for example, rockwool, asbestos yarn and cloth, asbestos millboard, rope lagging, packings and jointings, plastic finishing and insulating compositions and asbestos reinforced plastic sheeting, insulation; this Division operates in London, Liverpool, Dublin, and at Benoni, Transvaal. The Board Products Division incorporates Cape Building Products, Ltd., Uxbridge, makers of 'Asbestolux' board and the well-known Uxbridge Flint Bricks, Harefield Lime Company, producing lime for brick manufacture, and Marinite, Ltd., London and Glasgow, who make the popular 'Marinite' asbestos sheet.

Companies operating in the Engineering Division include Small and Parkes, Ltd., Manchester, concerned with brake and clutch linings, disk brake friction pads for automotive and industrial applications, fanbelts, engineering plastics; others trading elsewhere in Britain, in Brussels, and at Benoni South, Transvaal, are concerned with general garage equipment. That at Fareham, Hampshire, is concerned with water jet propulsion units for pleasure and commercial craft. There is a separate Overseas Division, based in Chicago, Toronto and Turin, which handles the sale of various asbestos products. Associated companies, concerned mostly with packings, jointing and insulating products, are located in Argentina, Canada, France, and elsewhere. This information about the activities of the Group is chronicled in the house journal, *Cape Magazine* (14, No. 3; Autumn 1965. 114 Park Street, London, W.1). Although most of this periodical is concerned with internal staff matters, from United Kingdom and overseas centres, a few short articles are of wider interest, one dealing particularly with the new rules (1965) governing structural fire pro-

tection in passenger and cargo ships, another with the safety precautions against accidents operating in the several factories belonging to the Group.

Forest Diseases and Insects

A GREAT deal of effort and investment is being directed to increasing forest production, but there are certain factors which are reducing the desired results. Many of these factors were discussed at a symposium held under the aegis of the Food and Agriculture Organization and the International Union of Forest Research Organizations at Oxford during July 1964 on "Internationally Dangerous Forest Diseases and Insects" (*Unasylva*, 19 (3), No. 78; 1965. Food and Agriculture Organization. 3*s*. 3*d*.). Very little factual information is available on losses due to these causes, but in the United States it was estimated in 1952 that they accounted for 35 per cent of the gross annual growth. Although old natural forest stands suffer most from decay and insect-caused mortality, the main concern of the future may be in the man-made forests, many of which are characterized by exotic species in pure, even-aged stands. Thus new problems are possibly being created. Of the various control measures likely to be practical on a forest scale, it seems that the so-called 'natural' ones hold certain advantages. Appropriate silviculture and forest management can manipulate the species, stand composition and rotation and so help prevent disease and insect damage. This really involves no extra cost and the same may be said of biological control measures which can be self-perpetuating. On the other hand, although chemical control has the advantages of being rapid, easily applied and available for use against many insects and fungi, its economics are complex and its possible side-effects tend to strike a warning note. Very sound recommendations were passed at the symposium and these included the need for more pathologists and entomologists, for more research and the quantitative evaluation of losses, for the certification of seed, the quarantine of plants and their disinfection and disinfestation and for annual reports from all countries on disease and insect conditions. This volume of *Unasylva* is a very fine synopsis of the main subjects discussed at the symposium. It is to be followed by the publication in two volumes of the individual papers and by a third volume on *Diseases of Widely Planted Forest Trees*. These will make available a great deal of useful information on subjects that are becoming more and more important in forestry practice.

Vegetation Types

MAPS of vegetation types can be of great value to the silviculturist and forest manager because they indicate site conditions, and site is a very important factor influencing production. The need for more detailed maps of vegetation types for parts of the Swiss Jura lying to the north-west of Lake Neuchâtel came about as a result of old silver fir stands suffering from the drought years of 1945–50. These stands, with southerly aspects and situated on shallow, calcareous soils, began to perish when, in their weakened state, they suffered from bark beetle attack (*Ips curvidens*). Thus, the Forest Service was faced with reforestation work, and so it was decided to make a detailed investigation of the natural vegetation of the region. This was done during the 10-year period ending in 1961 and the results are now available (*Extraits de la Carte Phytosociologique des Forêts du Canton de Neuchâtel*. Par Jean-Louis Richard. Commission Phytosociographique de la Société Helvétique des Sciences Naturelles. Matériaux pour le levé Géobotanique de la Suisse, Fascicule 47. Pp. 48+1 carte. Berne: Editions Hans Huber, 1965. 25 Sw. francs). It is claimed that in most of the forests of the Swiss Jura, man has nowhere degraded the natural vegetation to such an extent that it is irreversible. Indeed, even some changes in the woody vegetation have scarcely affected the herbaceous cover and the soil, and so there is little difference between the actual and the potential vegetation. Thus, where potential and not actual vegetation has been mapped, this has been done without fear of any risk of serious error. Four blocks of forest totalling more than 26,000 hectares were examined and their physical features, geology, soils and vegetation are described. Twenty-eight natural forest associations are listed, together with their characteristic species and notes on the soils. The vegetation type map with three blocks on a scale of 1 : 25,000 and one at 1:10,000 shows a wealth of detail and the reproduction is excellent. It is true to say that the entire work and its usefulness are typical of the efficiency that is associated with Swiss forestry.

Physiodormancy

DR. JOHN WIEBE, of the Horticultural Experiment Stations, Vineland Station, Ontario, has written to the Editor as follows: "All deciduous, temperate zone, perennial plants cease growth and enter dormancy at some time in summer or autumn. They remain dormant until growth begins again in spring under favourable moisture and temperature conditions. Frequently, temperature and moisture conditions in late summer and autumn are favourable for the continuation of growth, yet the plant remains dormant. If a dormant plant is brought into a greenhouse before its rest period, or cold period requirement, has been satisfied, it will remain dormant. Once the rest period has been satisfied by exposure to a suitably low temperature for a sufficient time, the plant is capable of resuming growth as soon as it is in a favourable environment. Because of continuing unfavourable temperature, it may however, and usually does, remain dormant for some time after its rest period has been satisfied. Because 'rest period' or 'cold period requirement' are ambiguous terms, I propose the term 'physiodormancy' for that component of the dormancy of a plant which is controlled by physiological or biochemical agents. Thus, a plant is said to be physiodormant when it will not start into growth at normally favourable conditions of moisture and temperature. The plant may continue to remain dormant, when it is no longer physiodormant, if temperature or lack of moisture prevents the resumption of growth".

Scientific Research

Scientific Research is a new addition to the list of monthly magazines which may be received gratis by those actively engaged in research in physics, chemistry or the life sciences. J. D. Luntz, editor and publisher of the magazine for McGraw-Hill, Inc., states in the first issue (January 1966) that the contents provide interpretative commentary on technical developments, selected technical articles, and new product information of specific use to experimenters. The feature article in the first issue is by C. Laverick on superconducting magnets, and the new products section consists of comprehensive surveys of commercially available (English, American and Japanese) storage oscilloscopes and American signal-averaging computers, together with a preview of some of the instruments which were exhibited at the Physics Show in New York during the annual meeting of the American Physical Society and American Association of Physics Teachers during January 26–29, 1966. A literature survey and reader service card are included. Three new improved designs of electron-microscopes, computer time-sharing, and a report on the disastrous fire that wrecked the Cambridge (Massachusetts) electron accelerator bubble chamber hall in July 1965, form the main features of "Science Roundup", the section dealing with recent developments.

Acta Physica

Acta Physica, devoted to the publication of original research work in the field of theoretical and experimental physics, is published by the Hungarian Academy of Sciences. Contributions deal with theoretical problems of the principles and applications of quantum mechanics, quantum chemistry, solid-state physics, thermodynamics and statistical mechanics, elementary particles, and experimental investigations in spectroscopy, crystal physics and nuclear and elementary particle physics. Papers are printed in English, German, French or Russian, with abstracts in various languages. Beginning in 1966, *Acta Physica* will appear in two volumes annually, each containing approximately four hundred pages, with four issues per volume. The subscription rate per volume is £3. The editor is P. Combás and the editorial board consists of Z. Gyulai, L. Jánossy, L. Kovács and K. Novobátzky.

New Members of the Advisory Council on Technology

Mr. D. K. Fraser, of G. A. Harvey and Co. (London), Ltd., and Mr. A. Siddall, of Joseph Lucas, Ltd., have been appointed members of the Advisory Council on Technology. They replace Lord Brown, who resigned on appointment as Minister of State at the Board of Trade, and Prof. M. J. Lighthill, who resigned on appointment as Honorary Physical Secretary of the Royal Society.

Scholarship at the National Vegetable Research Station

Applications are invited by the National Vegetable Research Station for a postgraduate scholarship tenable at the Station from October 1. The purpose of the scholarship is to enable the recipient to pursue further studies and to obtain training in one of the following lines of research in progress at the Station: biochemistry; biometry; ecology and control of weeds; entomology; plant pathology. The scholarship, which is of the value of £600 per annum, will be awarded for two years, with possible extension for a third year. Further information can be obtained from the Secretary, National Vegetable Research Station, Wellesbourne, Warwick. The closing date for receipt of applications is March 31.

Smithson Bicentennial Addresses

The Smithsonian Institution has announced that the eleven addresses delivered at the scholarly sessions of the James Smithson bicentennial celebration, held in Washington, D.C., during September 16–18, 1965 (*Nature*, 208, 320; 1965), are to be published in a volume now in the press. The collection will include papers by James S. Bruner, Herbert Butterfield, Sir Kenneth Clark, Ian McTaggart Cowan, G. Evelyn Hutchinson, Arthur Koestler, Claude Lévi-Strauss, Lewis Mumford, J. Robert Oppenheimer, Stephen E. Toulmin, and Fred L. Whipple, together with an introductory essay by S. Dillon Ripley, secretary of the Smithsonian. Readers of *Nature* have already had the benefit of a preview of a few of the papers (208, 923, 1033, 1036, 1145; 1965; and 209, 10; 1966). The book is scheduled for publication in the spring of 1966 by Simon and Schuster, New York, in association with the Smithsonian Institution. Further information can be obtained from the Editorial and Publications Division, Smithsonian Institution, Washington, D.C.

University News:

Birmingham

Mr. M. H. Loretto has been appointed lecturer in the Department of Physical Metallurgy. Dr. G. Sweeney has been appointed senior Research Fellow in the Department of Mechanical Engineering. The following Research Fellows have also been appointed: Mr. D. K. Davies (geology); Mr. J. A. F. Wickramasinghe (physiological chemistry).

Liverpool

Prof. D. Hull, professor of physical metallurgy, has been appointed to the Henry Bell Wortley chair of metallurgy, on the resignation of Prof. W. S. Owen. The following lecturers have also been appointed: Mr. K. G. Evans, Dr. G. R. Jones and Mr. D. P. Sen Gupta (electrical engineering and electronics).

Manchester

Dr. J. G. Davies, reader in radio astronomy, has been appointed to an additional chair of radio astronomy.

Sheffield

The following lecturers have been appointed: Dr. J. D. Harry (physiology); Dr. G. M. Birtwistle (electronic computation in the Department of Applied Mathematics).

Sussex

The following appointments have been made: *Professorships:* Mr. J. F. C. Kingman (mathematics and statistics); Dr. F. J. Bayley (mechanical engineering); *Lectureship:* Dr. S. Shall (biological sciences); *Senior Research Fellowships:* Dr. M T. Gillies and Dr. K. A. Stacey (biological sciences).

Announcements

Mr. J. F. Gaitens has been appointed technical assistant to the scientific director of the Universities Federation for Animal Welfare.

Prof. T. F. Dixon has resigned from his position as head of the Department of Biochemistry in the University of Singapore in order to join the Eastern Mediterranean Region of the World Health Organization.

A seminar on "Atmospheric Physics" will be held by the American Institute of Physics in Washington on March 14. Further information can be obtained from Eugene H. Kone, American Institute of Physics, 335 East 45 Street, New York 17.

A conference on "Historical Aspects of Microscopy" will be held by the Royal Microscopical Society at Oxford on March 18. Further information can be obtained from the General Secretary, Royal Microscopical Society, Tavistock House South, Tavistock Square, London, W.C.1.

The 1965 Guthrie Lecture of the Institute of Physics and the Physical Society will be delivered by Dr. J. B. Adams (director of the Culham Laboratory) on the subject "Nuclear Fusion Research" on March 28. Further information can be obtained from the Meetings Officer, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A meeting of the Biochemical Society will be held at the University of Hull during March 24–25. The programme will include a colloquium on "The Metabolism of C_1 Compounds", a discussion forum on "Mucopolysaccharides", and a visit to the Biological Laboratories of Reckitt and Sons, Ltd. Further information can be obtained from the Administration Officer, the Biochemical Society, 20 Park Crescent, London, W.1.

The anniversary meetings of the Chemical Society will be held in Oxford during March 28–31. The programme will include symposia on complexes of the heavy donor atoms, contemporary topics in organic chemistry and methods of studying molecular interactions in gases, liquids and solids, a discussion on the uses of programmed learning in the teaching of chemistry to degree standard, the Robert Robinson Lecture on "Some New Developments in the Chemistry of Natural Colouring Matters", to be delivered by Lord Todd, and various tours and visits. Further information can be obtained from the General Secretary, the Chemical Society, Burlington House, London, W.1.

THE BRITISH COUNCIL

THE feature article accompanying the annual report for 1964–65 of the British Council is this year concerned with libraries and library development (*Annual Report of the British Council, 1964–1965*. Pp. vii+99+12 plates. London: The British Council, 1965. 2*s*. 6*d*.). It contrasts the present position of libraries in Britain where normally upwards of 250,000 titles are in print at the publishers, 7,000 periodicals are available, and library co-operation offers access to more than 100 million books, and the public library service with a stock of about 80 million volumes issued more than 500 million books on loan from 40,000 points of service with the position of British Council libraries abroad and the work of the Council's libraries. The Council now maintains 141 British libraries overseas and sends regular supplies to a further 55. These 196 libraries, including 62 in Asia and 42 each in Africa and in Europe, cover 83 countries; 252,372 volumes were supplied to them in 1964 and they lent about 4·5 million books. Their three major functions are to provide a ready and comprehensive service of information on any subject falling properly within the Council's field; to keep the serious student using them in touch with recent British developments in his or her field; and to support the Council's work in teaching English with technical works and dictionaries and with appropriate text-books at all levels. They are built up over the years on the detailed advice of Council staff working in the field. In India and Pakistan, and on a smaller scale in Ceylon, Nigeria and Trinidad, the Council has set up special collections of multiple copies of English text-books which are prescribed reading for local university and other courses, concentrating on aspects of science, technology, economics and social sciences, with some medicine and dentistry. In India alone, some 60,000 such text-books have thus been made available to the libraries of 150 universities and colleges.

Use is made of some 2,200 periodicals published in Britain, and subscriptions to these and annual reference books total nearly 50,000. More than 150 professional librarians are now employed by the Council, and the trained librarian occupies a key position in developing the Council's library services overseas. The Council is also giving special attention to the development of public libraries in the new Commonwealth countries, and in the past 6 years 22 schemes in 9 countries have been assisted. Some £370,000 has been spent on capital grants and other forms of aid under this scheme, and the projects have been uniformly welcomed by the Governments of the countries concerned. The grave shortage of qualified and experienced librarians, however, has been a constant brake on library development in all fields and is likely to constitute a limiting factor for some years to come which only assistance from overseas can remove. Even so, the Council is concerned as to whether sufficient is being done to expand library services in the developing countries of the Commonwealth.

The Council's budget of £10,736,000 for 1964–65 included £676,000 from earnings and donations, grants of £5,388,000 from the Foreign Office, £3,977,000 from the Commonwealth Relations Office, £304,000 from the Colonial Office, £371,000 from the Ministry of Overseas Development, and £20,000 from the Board of Trade making up the remaining part. The Council also administered the expenditure on technical assistance schemes of £2·5 million from the Ministry of Overseas Development. There are now 60 posts for English language teaching experts in the Council's career service at a cost of £280,000 a year and these activities tend to concentrate increasingly on training teachers. Television officers have been appointed in Ghana, India, Iran, Kuwait, Nigeria and the Sudan and, in 1965, in Latin America and Ethiopia, while places for nearly 600 teachers of English from overseas are provided in summer schools in Britain. The Council helped to finance a project to develop programmed materials for teaching English, and a large-scale enquiry conducted by the National Foundation for Educational Research into the language difficulties of overseas students and collaboration with the British Broadcasting Corporation in the production of films for teaching English continued.

Further requests were received during the year, particularly from Commonwealth countries, for assistance in training science teachers and in the reform of school curricula in scientific subjects, and the Council has created six posts for scientific officers in East and West Africa. Of some 713 specialist tours, advisory visits and delegations arranged during the year, 113 were concerned with science and technology, 91 with medicine and 240 with education. A scheme of exchanges between British universities and the Centres of Advanced Study in India was started. Of 63 awards toward the cost of travel between Commonwealth countries, 43 were to university teachers on leave, 15 to distinguished scholars invited by universities for short visits and 10 for postgraduate university workers with research grants. Under the foreign scheme, 130 short visits were paid by senior members of university staffs, 3 longer visits and 103 visits under the younger research workers interchange scheme. Of 11,130 overseas visitors to Britain assisted by the Council, 2,664 were concerned with science and technology, 1,284 with medicine, 2,440 with social studies, and 2,612 with education.

Further progress is reported with the Overseas Students Welfare Expansion Programme, and by August 31, 1965, provision for more than 3,750 places had been approved since the scheme was launched in 1961, and grants for hostel development totalling £2,525,000 had been made. An encouraging feature is the extent to which the welfare needs of overseas students are being met by the institutions in which they are studying. More than 340 young Russians visited Britain in 1964–65 under the student exchange programme; and nearly 500 final-year students from Latin America, many of whom were concerned with developments in industry and technology, came to Britain under a programme initiated in 1962 in association with the Institute of Directors. Of the 9,923 overseas students met on arrival, 6,221 were from the Commonwealth and 1,713 from Colonial territories. Permanent accommodation in Council residences was arranged for 297, in lodgings for 6,125, and in university and other hostels and halls of residence for 2,026, apart from transit or temporary accommodation. Hospitality was accepted for 14,567 students; 16,200 were members of Council centres, 2,877 attended holiday courses of 7–10 days, and 22,200 attended weekend courses, study units and surveys. In October 1964, two additional Council scholarships were created to provide undergraduates from the Federal Republic of Germany with an opportunity of taking a first degree at a British university, and the present estimates (1965–66) provide for an increased programme of youth exchange between Germany and Britain.

THE BRITISH RADIOLOGICAL PROTECTION ASSOCIATION AND THE JOINT HEALTH PHYSICS COMMITTEE

SCIENTISTS of many specialities are concerned with some aspects of what, for want of a better name, has usually been referred to as 'health physics'. This may be taken to be the investigation of problems of radiological protection including, for example, radiation dosimetry and operational techniques connected with the use of ionizing radiations in industry, medicine and scientific research. Some co-operation of the various appropriate learned societies and other bodies concerned was therefore felt to be desirable, and in December 1961 the Joint Health Physics Committee was set up to co-ordinate the arrangement of symposia in this field. This Committee had representation from the British Institute of Radiology, the British Occupational Hygiene Society, the Faculty of Radiologists, the Hospital Physicists' Association, the Institute of Physics and the Physical Society, the Radiological Protection Service, and the Health and Safety Branches of the Central Electricity Generating Board and the United Kingdom Atomic Energy Authority. After its formation in 1963, the Society for Radiological Protection was also represented.

This co-operation was fruitful, each organization in turn arranging a symposium open also to interested members of the other organizations. Some twelve symposia have been held during the period 1962–65 with attendance between 150 and 300, the distribution between the various specialities varying with the nature of the subject.

The Health Physics Society, which was formed in the United States in 1955, was intended to be an international organization. In fact, by 1964 it did have some 20 per cent of its membership in some fifty countries outside the United States, and a number of national sections (including the Society for Radiological Protection in the United Kingdom) had been formed. However, it was apparent that other national or regional health physics organizations were also being formed and, with the initiative of Dr. K. Z. Morgan, of the Health Physics Society, discussions were started with representatives of many countries for the formation of an International Radiation Protection Association to promote international scientific co-operation in health physics and, at intervals, to arrange international meetings in this field. A provisional constitution was agreed at a meeting in Paris in December 1964, under which the International Radiation Protection Association was to consist of an affiliation of national societies (one from each country or region) with individual members of these societies having, as appropriate to their qualifications, either full or associate membership of the Association.

To meet this new situation, and after detailed discussions between the societies concerned with the Joint Health Physics Committee, it was agreed to form instead the British Radiological Protection Association. This is an affiliation of learned societies concerned with radiological protection, formed to affiliate itself to the International Radiation Protection Association as the associate society for the United Kingdom. For a small annual subscription (at present 10*s*. per annum) interested members of any of the constituent societies may then join the British and also automatically the International Radiation Protection Association as individual full or associate members, according to their qualifications as laid down in the constitution of the International Radiation Protection Association. The Joint Committee of the British Radiological Protection Association has representation from each of the constituent societies (together with one or two non-voting co-opted members) and will function in place of the Joint Health Physics Committee to co-ordinate the arrangement of symposia on health physics subjects in Britain. It will also arrange for discussion of relevant topics with the British representatives of the British Radiological Protection Association on the executive council of the International Association, who, under the constitution, will have been elected by a ballot of the individual full members of the Association.

The founder constituent societies of the British Radiological Protection Association are the British Institute of Radiology, the British Occupational Hygiene Society, the Faculty of Radiologists, the Hospital Physicists' Association and the Society for Radiological Protection (now no longer a section of the Health Physics Society). The Society of Radiographers has also been accepted as a constituent society. That there is general support for the Association is evident from the fact that already more than three hundred individual full members have been registered and accepted for membership of the British and International Associations. This number will entitle the British Radiological Protection Association to five votes on the executive council of the international body.

Affiliations to the International Radiation Protection Association have now been accepted from a total of eleven societies, including organizations in France, the United States, Luxembourg, Scandinavia, Japan, United Kingdom, Belgium, Israel, Italy, Netherlands and Central Europe, and other applications are pending. Thus, the International Association is well established and its first International Congress is to be held in Rome in September 1966.

Meanwhile, the Joint Committee of the British Radiological Protection Association is planning two symposia in the United Kingdom in November 1966, one to be organized by the Faculty of Radiologists on "Radiation Genetics", and the other to be organized by the British Occupational Hygiene Society on the "Hazards Associated with the Use of Lasers". It is to be hoped, therefore, that such co-operation, both nationally and internationally, will be of general and scientific value to those concerned with the various aspects of radiological protection.

Further details of the British Radiological Protection Association and its functions can be obtained from any of the constituent societies, or from the honorary secretary of the Joint Committee, Mr. R. Oliver, the University Radiation Protection Office, 15 Parks Road, Oxford.

R. Oliver

NUCLEAR AND ENGINEERING CERAMICS

THE position of ceramics in nuclear engineering is now well established. The same cannot be said for their structural applications in engineering if the relative number of papers on these two aspects presented at the meeting of the Basic Science Section of the British Ceramic Society held at the Atomic Energy Research Establishment, Harwell, during October 25–27, 1965, is truly representative. Of the thirty papers presented, only five dealt with potential non-nuclear applications. Mr. N. Parr (Admiralty Materials Laboratory, Poole, Dorset) discussed the difficulties encountered in attempts to establish the technology of reaction-bonded silicon nitride and its

application as a structural engineering material. Of particular interest was the philosophy lying behind his engineering designs to take into account the brittle nature of his material. The complexities attending the pyrolytic preparation of silicon carbide formed the main theme of the paper presented by P. Popper (British Coke Research Association, Stoke-on-Trent). This process, which superficially seems quite simple, was obviously sensitive to a number of process variables which had a considerable effect on the structure and hence the properties of the deposited material. There were three papers dealing with mechanical properties as such, two concerning themselves with beryllia and one with silicon carbide. Quite respectable strengths are now available in carefully fabricated polycrystalline ceramics. The paper by N. A. Hill, J. S. O'Neill and D. T. Livey (Atomic Energy Research Establishment, Harwell) showed that by control of grain size, moduli of rupture of approximately 50,000 lb./in.^{2} were obtained in beryllia. W. P. Rotsey, K. Veevers and N. McDonald (Australian Atomic Energy Commission, Lucas Heights) showed that in addition to grain size, surface preparation and the presence of water vapour were critical features in determining the room temperature strength of beryllia. Results of investigations of the delayed fracture in air of a self-bonded silicon carbide reported by J. C. V. Rumsey and A. L. Roberts (University of Leeds) showed that delayed fracture behaviour could be adequately correlated phenomenologically and that at elevated temperatures well-defined primary and secondary creep stages were exhibited.

With respect to the nuclear aspects of the meeting, it is interesting to compare the nature of the papers presented at this meeting with those presented at a very similar meeting at the same venue 4 years previously. The general headings are approximately the same, but the emphasis has, as one would have expected from the rapid progress in the nuclear field, changed considerably. Whereas 4 years ago interest was mainly centred on the fabrication and properties of uranium and plutonium oxide ceramics with a little attention being paid to the carbides, on this occasion practically no attention was given to the pre-irradiation, preparation and characterization of oxide ceramics, the main interest in these areas now lying with uranium and plutonium carbides with a little attention being given to other uranium compounds. The papers by D. George and N. R. Williams (Atomic Energy Research Establishment, Harwell) and by J. M. Horspool and N. F. Rose (Dounreay Experimental Reactor Establishment, Caithness) showed clearly that the preparation and fabrication by sintering of uranium monocarbide and uranium plutonium monocarbide were close to becoming well-controlled fabrication routes, most of the problems associated with the preparation of fine powders, their handling and the selection of a suitable binder, having been overcome. In both these papers the use of nickel as an additive to promote sintering to greater than 95 per cent theoretical density at temperatures as low as 1,550° C was advocated. It became quite clear, however, that the true role of nickel as a sintering promoter was far from understood, and this was emphasized by the paper of B. L. Eyre, A. F. Bartlett and D. Barry (Atomic Energy Research Establishment, Harwell) which described a transmission electron microscope investigation of sintered uranium monocarbide with and without the nickel additions. Differences in structure were observed and possible effects on sintering behaviour were discussed again without any very definite final conclusions being reached.

The complexity of phase relationships in the uranium–nickel–carbon, uranium carbide–iron–nickel, and uranium carbide–iron–chromium systems was illustrated in a paper by S. K. Dutta and J. White (University of Sheffield). Probably the most interesting point which arose from this work was that solid uranium carbide was likely to be compatible at elevated temperatures with only a very limited range of iron–chromium alloys despite the fact that it was completely compatible with both iron and chromium. This situation arose as a result of the formation of the compounds $Cr_{23}C_6$ and UFe_2. The sensitivity to composition of the mechanical properties of uranium monocarbide and closely associated alloys was the basic theme of the papers by J. S. Pottinger, M. C. Regan and H. J. Hedger (Atomic Energy Research Establishment, Harwell) and A. Accary, P. Magnier and M. Marchal (Commissariat à l'Énergie Atomique, Saclay). The former authors used hot hardness measurements to show that hypostoichiometric compositions softened rapidly above 600° C, while hyperstoichiometric compositions showed a slower decrease of hardness up to about 1,000° C. Partial substitution of tungsten, niobium and vanadium for uranium in the carbides was particularly effective in increasing the resistance to deformation by indentation. At higher temperatures the French investigators showed that mechanical behaviour was strongly dependent on the total carbon content and that at approximately 2,300° C the plastic properties were such that extrusion and die-forming were possible. Measurements of self-diffusion in uranium carbide were reported by H. M. Lee and L. R. Barrett (Imperial College, London), who concluded that the activation energy of bulk diffusion in the slower diffusing species, namely, uranium, was in good agreement with sintering kinetic data, but that the mechanism of creep was likely to be more complicated than that usually described as the Herring–Nebarro mechanism.

The growing importance of fuel in the form of microspheres (approximately 500μ diameter) was represented by papers dealing with the preparation, coating, evaluation and irradiation testing of sol gel oxide micro-spheres by R. G. Wymer and J. H. Coobs (Oak Ridge National Laboratory, United States), and the consolidation of carbon-coated fuel particles in a graphite matrix by hot pressing by G. H. Williams, J. B. Morris and D. W. Savage (Atomic Energy Research Establishment, Harwell). The use of sol-gel techniques for the preparation of very high density oxide spheres at relatively low temperatures was pioneered at Oak Ridge, and they have now extended their work both in scale and in scope to include plutonium dioxide, thorium dioxide–uranium dioxide and plutonium dioxide–uranium dioxide, rare earth oxides and curium oxides. These particles have to be coated usually with pyrolytic carbon to retain fission products and their incorporation into a matrix without cracking the coating is a delicate operation which has apparently been solved by the British authors.

Work reported on the irradiation behaviour of fissile ceramics was confined largely to uranium dioxide, as would be anticipated from its present pre-eminent position as a nuclear fuel. As was re-stated by R. S. Barnes and R. S. Nelson (Atomic Energy Research Establishment, Harwell) in their general paper on the behaviour of inert gases in ceramic fuels, structural changes have an overwhelmingly important effect on gas release. The paper by J. R. McEwan and J. Hayashi (Atomic Energy of Canada, Ltd.) detailed the effect of time, temperature and five other potential variables on isothermal grain growth in uranium dioxide. Of general interest was the observation that porosity elimination was not rate controlling so far as grain growth was concerned. The use of an arc image furnace to study columnar grain growth in a temperature gradient of uranium dioxide, both with and without additions of other oxides, was reported by T. J. Potter and C. A. Elyard. Matters relevant to the dimensional stability of uranium dioxide taken to high burn-ups were the subject of papers by B. T. Bradbury, J. T. Demant and Mrs. P. M. Martin (Atomic Energy Research Establishment, Harwell) and by J. D. B. Lambert (Atomic Energy Research Establishment, Harwell). The former authors were concerned with the nature and distribution of solid fission products in irradiated uranium dioxide. Above approximately 3 cent burn-up, white inclusions were found at grain

boundaries which contained a number of the solid fission product elements. Mr. Lambert reported on the irradiation behaviour of uranium dioxide particles in cermets at burn-ups in the range 5–12 per cent and was mainly concerned with the swelling which appeared to proceed eventually at an inexorable rate of about 1·7 volume per cent per 1 per cent of burn-up.

Detailed investigations of the behaviour of krypton gas bubbles introduced by ion bombardment in uranium dioxide using the electron microscope were described by G. H. Bannister, R. M. Cornell and B. M. Jeffrey (Central Electricity Generating Board, Berkeley).

There were more papers dealing with the irradiation behaviour of non-fissile ceramics than with any other single topic. Both gas release and dimensional stability were, as were fissile oxides, major topics for consideration. In-pile release of helium from beryllia had been investigated by Y. Carteret, J. Bareau and J. Elston (Commissariat à l'Énergie Atomique, Saclay), who showed that after a few hundred hours the release of helium attained a constant level. Measurements of the diffusional release of tritium from beryllia by fast neutron annealing had been made by K. T. Scott and L. L. Wassell (Atomic Energy Research Establishment, Harwell). The behaviour exhibited, namely, that of initial bursts followed by steady-state release, was very similar to that of inert gas in fissile oxides. Activation energies varied from 48 to 59 kcal/mole. Investigations of the nature of fast neutron-induced defects in single crystal alumina and in polycrystalline alumina and magnesia, using transmission electron microscopy, changes in lattice parameter, density and length were reported by R. S. Wilks *et al.* (Atomic Energy, Harwell), by M. Stevanovic and J. Elston (Commissariat à l'Énergie Atomique, Saclay) and by R. P. Thorn and V. C. Howard (Reactor Materials Laboratory, Culcheth). A still more sophisticated technique for studying irradiation-induced defects by the scattering of long wave-length neutrons was reported by D. G. Martin (Atomic Energy Research Establishment, Harwell), who showed that the smaller clusters often visible under the electron microscope as irresolvable dots probably contained less than thirty defects per cluster. The overall situation on irradiation effects in ceramic oxides was well summarized in a paper by B. S. Hickman and D. G. Walker, who discussed at some length correlations between the irradiation behaviour of beryllia, alumina and magnesia as well as zinc oxide. The irradiation behaviour of only one non-fissile carbide, namely, polycrystalline, self-bonded, porous, cubic, silicon carbide, was discussed by R. P. Thorn, V. C. Howard and B. Hope (Reactor Materials Laboratory, Culcheth) in terms of dimensional change and X-ray parameter measurements. The saturation growth obtained was, as is normal, a function of temperature and was paralleled by saturation effects in thermal conductivity. There was, however, an appreciably slower recovery on annealing of thermal conductivity compared with dimensions.

The meeting was organized by Dr. D. T. Livey of the Metallurgy Division, Atomic Energy Research Establishment, Harwell, and, as was apparent, received a considerable amount of international support. It was attended by 152 people and, as has now become the well-established form with the Basic Science Section meetings, approximately half were members of the Society and half were guests. The papers presented at this meeting will be published as a separate volume of the proceedings of the British Ceramic Society.

J. Williams

REVIEW OF THE FOSSIL RECORD

A SYMPOSIUM entitled "A Review of the Fossil Record", organized jointly by the Geological Society of London and the Palaeontological Association, was held at the University College of Swansea during December 20–21, by invitation of Prof. F. H. T. Rhodes, head of the Department of Geology. It was attended by some 160 members.

The meeting had been arranged in order to discuss a projected publication volume by the Geological Society, and in this respect it followed the pattern of the symposium on the Phanerozoic time-scale held at Glasgow in February 1964. The volume in preparation is to consist mainly of contributions by more than a hundred specialists, covering the whole fossil record, both plants and animals, organized into thirty chapters on a systematic basis. Each contributor was asked to recommend a classification of his allotted taxa, and to document the first and last reported fossil occurrence of each taxon. To do this thoroughly was thought to be a sufficient task, and it carried the implication that there was continuity of life between these first and last occurrences, even if no intermediate record had yet come to light. Thus, a survey of the ranges of taxa covering all fossils through geological time could be included in a single volume. It was left to the contributor in each case to decide on the degree of taxonomic sub-division; so in some cases families and genera, and in others, super-families or orders, have been recorded. In this way some idea of the diversification can be given, without departing from the minimum requirement for first and last documented records.

An editorial committee shared the systematic editing and maintained contact with specialist contributors. The committee also worked out a standard stratigraphical scale, so that data could be presented in a uniform way. To this end, questionnaires were first sent out, and after some discussion a scale was agreed on, admittedly arbitrary and temporary, for the use of the symposium only. However, some longer-term benefit may result from this, for although the scale was divided into units of about stage rank and did not attempt any tidy or final codifying of these units, the committee did nevertheless define the base of each selected unit reasonably precisely and unambiguously. This project demonstrated the need for a standard global stratigraphical scale, and illustrated the principle of defining units by single reference horizons at their bases. The degree of division of the stratigraphical scale was a compromise, being on the one hand too fine for much international correlation, and on the other too coarse to plot some precisely known records. The stratigraphical scale was used for a series of charts on which the ranges of taxa were plotted as lines joining first and last records. Some precision was also lost because presence only, and not position, within each division was plotted. These working charts were on display at Swansea, and will be re-drawn for publication in the forthcoming volume.

The object of the symposium meeting was to discuss issues relevant to this compilation. Eight main papers and several short prepared contributions were presented and will appear, with some of the discussion, in the symposium volume.

The symposium was introduced with a review of the origin and development of Pre-Cambrian life and the base of the Cambrian system by J. W. Cowie. Speculation on the origin of life on this planet, as related to hypotheses of the composition and state of the hydrosphere and atmosphere, was briefly surveyed, and was followed by a review of the earliest organized structures in rocks. Mention was made of the recent discovery by Barghoorn of organized carbon residues about 3,000 m.y. old, possibly

older than the better-known stromatolitic dolomite of McGregor from Bulawayo which has been dated only by correlation with distant rocks via 2,700-m.y.-old granite. In rocks less than 2,000 m.y. old, stromatolitic, algal and acritarchal structures are common. The first faunas so far established may not be much older than established Cambrian; how much older they are raises the question of the biostratigraphic definition of the base of the Cambrian. The distinct and now well-known *Ediacara* fauna is only marginally older than archaeocyathid or trilobite-bearing Cambrian. Thus, shelled brachiopods could be the oldest animal fossils yet known, the newly discovered obolids from arctic Canada having been uncertainly argued, from radiometric evidence, to be about 700 m.y. old. The degree of (? explosive) evolution of the known Lower Cambrian fauna was then examined in relation to various hypotheses.

In discussion, it was pointed out by P. C. Sylvester-Bradley that a distinction should be made between complex organic chemicals preserved in ancient rocks, which might be abiogenic, and relics of organized life. It was argued by R. Goldring that trace fossils (except, for example, burrows) were commonly formed at the sediment–water interface, which itself might not be generally preserved. This would account for the discrepancy between ranges of fossils and traces of presumed similar animals. Even so, there was a marked increase in traces of biological activity with the appearance of trilobites.

A computer analysis of the fossil record was presented by B. M. Funnell and J. L. Cutbill. The committee had decided that the large amount of data to be assembled according to a common pattern justified some attempt at computer analysis. It was only possible to report at the meeting results based on the unedited charts already submitted; however, 1,566 taxa from these were used, and it seemed unlikely that later submissions would alter the results in any substantial way. Taxonomic rank depends perhaps as much on the history of palaeontological investigations as on any biological hierarchy, and therefore no particular attempt was made to correct according to their systematic rank the taxa which had been selected by contributors, except that in three cases where large numbers of families had been documented in a limited part of the stratigraphical column these were reduced to super-families. Errors affecting the ranges of taxa were inevitable, not only because of the many limitations of the fossil record, but also as the result of the systematic attribution of fossils and the history and geography of palaeontological research. A significant bias was inevitably introduced by the fact that living representatives of taxa, rather than fossils, had been documented for the latest stratigraphical unit, thus heavily over-weighting this latest interval by comparison with all other intervals, which depended solely on the fossil record. For analyses of ranges standard units were taken as equal, although many were known geochronologically to be unequal, and others were not sufficiently known. The known units averaged about 5–6 m.y. back to the Triassic, and 5–10 m.y. back to the Devonian, increasing to 15 or even 30 m.y. for the early Palaeozoic ages. The authors were under no illusions about the limitations of what could be obtained by numerical abstracting and presentation of the data (for example, in histograms, with successive smoothing), but nevertheless it was possible to draw some general conclusions from the tabulations presented. Frequencies of all taxa, initial or final records per stratal unit with major taxa taken separately or totalled, were not random; some trends were noticeable, reflecting rapid diversification in early Palaeozoic time and a distinct Palaeozoic mode, with a marked 'low' in the curves at about the Permian/Triassic boundary. The Mesozoic/Cenozoic boundary was not so distinctly marked.

Lower Palaeozoic appearances were discussed by M. R. House, who first commented on what the computer analyses had shown independently, namely, the genius of John Phillips 125 years ago in distinguishing the broad Palaeozoic, Mesozoic and Cenozoic divisions of life. House surveyed the progress and diversification of most major taxa through Palaeozoic time. In assessing claims for an evolutionary explosion it would be important to distinguish between taxonomic diversification and the numerical abundance of individuals within each taxon. However, an initial multiplication of genera to a high early maximum was followed by a slower decline. Moreover, early diversification was more rapid in higher ranks of taxa. Although rocks of Cambrian age have yielded records of most phyla, the Ordovician might well prove to be the time of most marked explosion and proliferation. The detailed pattern was probably controlled ecologically, and might have been markedly affected by the feeding habits of different groups.

By reference to the *Dalmanellacea*, V. G. Walmsley showed how relatively minor and continuous taxonomic revision could produce major changes in range charts. But, as pointed out by B. M. Funnell, when many records are combined small changes will be self-cancelling and so will not seriously affect the kind of statistical study conducted.

Permo–Triassic changes were discussed in a paper by F. H. T. Rhodes (read by M. J. S. Rudwick), who argued first that the Permian was a time of rich and diversified faunas, even those that were shortly to become extinct; thus there was little prior indication of impending changes. Although substantial extinctions took place towards the end of Permian time, the noticeable effect was due to many gaps not being immediately filled, so that early Triassic faunas lacked variety and contrast. Certainly, although none of the many hypotheses for these changes has yet been substantiated, and few continuous marine successions across the boundary are known, the marked change in the fossil record does not appear to be an artefact and demands explanation.

Triassic/Jurassic vertebrate changes were discussed by C. B. Cox, who showed that the most fundamental changes on land took place in Triassic time, though correlation of some of the continental strata is uncertain. Extensive adaptation to marine conditions was a distinctive feature of Triassic time. This pattern gave some coherence to the Mesozoic era so far as vertebrates were concerned.

Cretaceous–Tertiary marine faunal changes were discussed by J. M. Hancock, who limited himself to a careful study of the commonly accepted dramatic extinction of ammonites and possible continuation of belemnites. Decline was already evident in Campanian time and, indeed, gradual extinction was also taking place in Maestrichtian time, although world-wide regression at the close of Maestrichtian time obscured the record. Many important occurrences have been recorded recently from Danian and Upper Palaeocene rocks so that changes, while gradual in detail, were yet distinctive when viewed on a sufficiently broad scale.

G. M. Phillip commented on the record of the Echinoids, which evolved slowly through Ordovician to Triassic time, with about one new family per period, and then dramatically diversified in Lower Lias time, with new families continuing to appear at about 15 times that rate to the present day.

Plant–insect relationships were next discussed. The apparent dramatic changes in the insect record are largely attributed to the relatively few rich fossil insect horizons, but some established stages of insect evolution were nevertheless outlined by J. M. Smart. A number of suggestions were made by N. F. Hughes about plant evolution and its possible relationship to insect development. Most insects depend directly on plants for food, and the suggested later Cretaceous development of angiosperms may not have had much impact on insect evolution because the pre-angiosperms (pteridophytes and gymno-

sperms) provided a similar habitat when equatorial. A critical stage may have been reached with the emergence of tall land plants in Devonian time; insects would have crawled up these plants and developed flight. The important diversification of reproductive structures in plants in early Carboniferous time was probably a protective response to attack by insects, which themselves became adapted in diverse manners. Insect pollination could have begun in Permian time.

The last principal contribution, biochemical evolution and the fossil record, by L. B. Tarlo, reviewed a rapidly expanding field of investigation, largely consequent on recently developed techniques using amino-acid analysis. Comparative biochemistry has long provided some independent taxonomic criteria, but only recently has the systematic investigation of the biochemical record of the rocks been stimulated by the possibilities of protein taxonomy. With what reliability particular combinations of amino-acids may be used to infer the presence of, for example, collagen is still uncertain, but this line of investigation promises well. It is complicated by the discovery that not only do many fossils yield rich biochemical results, but so do their enclosing rocks; hence the source of any particular compound is often difficult to determine.

A. Hallam, from studies of strontium/calcium ratios in cephalopod shells, suggested that later Palaeozoic nautiloids may be related to more 'primitive' forms than goniatites.

Throughout the discussion the basic questions of evolutionary cause and effect recurred, often inconclusively. Linguistic care was necessary to avoid 'loaded' descriptions such as one form 'ousting' another from its 'ecological niche'. But not all was negative. Some correlation between changes due to physical environment and those due to selective pressure for evolutionary adaptation seemed reasonable. If this were pressed in terms of what is becoming known about the inevitable interplay of tectonic, eustatic, gradational and climatic changes, for example, then the evident rate of biological change may be partly explicable.

It is hoped that the whole symposium and volume will stimulate palaeontologists and others to extend this study to progressively lower levels of taxa as a contribution to the record of evolution of the biosphere as a whole.

AND

G. FERRARA
Nuclear Geology Laboratory, University of Pisa, Italy

In a survey of the British Caledonides, Read[1] emphasized the need for more information on the many aspects of Caledonian magmatism in Britain. He briefly discussed the few available isotopic ages for the Caledonian granites of the 'metamorphic' and 'non-metamorphic' belts, but pointed out that further determinations were clearly required. More recently, Fitch *et al.*[2] have published geochronological data relating to magmatic activity within the 'non-metamorphic Caledonides' of North Wales, and have reviewed aspects of Caledonian orogeny and metamorphism in Britain[3,4]. This article reports the results of isotopic age determinations on biotites from hornfelses associated with the Tan-y-grisiau 'microgranite', Ffestiniog, North Wales, and briefly discusses their significance in investigations of Caledonian magmatism.

Several authors[5–10] have made reference to the Tan-y-grisiau intrusion, but little detailed work has been published concerning its petrology, form and age. Recently, one of us (J. E. T.) has made a petrological and petrochemical examination of the intrusion and its aureole. During this work biotite-bearing metamorphic rocks were collected from the south-east margin of the intrusion (350 yd. west of Brynmelyn cottage, *SH*687430) which have since proved suitable for age determinations by the potassium–argon and the rubidium–strontium methods. The samples are representative of two rock types: a biotite-rich contact hornfels and a biotite-bearing xenolithic rock included in granite veins penetrating the country rock. Biotites in the granite itself were examined in thin-section but were found to be extensively chloritized and unsuitable for age determinations. The dating of an intrusion solely by means of measurements on associated hornfelses does not appear to have been reported previously, although Erickson and Kulp[11] and Hurley *et al.*[12] have given data for fine-grained hornfelses, which agreed well with results from associated igneous mica. Whole-rock determinations on the granite itself are in hand.

* Present address. Department of Geology, University of Leeds.

Potassium–argon determinations were made at Oxford, where a Franz isodynamic separator was used for mineral separation. Argon was determined on a Reynolds mass spectrometer using an isotope dilution technique with argon-38 tracer. Potassium was determined by flame photometry. The analytical precision for both elements is estimated as ±2 per cent from replicate determinations. The uncertainties in the ages given in Table 1 are based on this figure, giving a precision of ±3 per cent in the Ar/K ratio. The rubidium–strontium determinations were done at Pisa. The biotite sample used for the determination on the contact hornfels was taken from a separation done at Oxford, part of which had already been used for duplicate potassium–argon determinations. The xenolithic biotite was separated at Pisa using a Franz separator. A selected sample was further purified by grinding under alcohol and resieving. The rubidium and strontium contents of the biotite were determined by an isotope dilution method using an Atlas *CH*4 mass spectrometer with normal collector. The analytical results are given in Table 2.

The 'uncorrected ages' in Table 2 are based on an assumed normal $^{87}Sr/^{86}Sr$ ratio of 0·712 at the time of metamorphism. Because of the difference between these and potassium–argon ages, it was decided to make some 'whole-

Table 1. Potassium–Argon Data

Sample No. and description	K (per cent)	^{40}Ar (p.p.m.)	Atm Ar / Total Ar (per cent)	Age (m.y.)

JET/2 Xenolith (biotite)	327 ± 6	48·9 ± 0·8	0·590 ± 0·041	0·15	433 ± 30	429

$t_{\frac{1}{2}} = 4{\cdot}7 \times 10^{10}$ yr.

rock' rubidium–strontium measurements on the hornfelses. The method by which such measurements can be used to give a calculated age which takes account of variation in isotopic composition of strontium at the date of metamorphism has been demonstrated for the Moine Series by Long and Lambert[13].

For *JET*/1 the whole-rock measurements gave the ratios: total Rb/Sr = 0·8 by weight, $^{87}Sr/^{86}Sr = 0{\cdot}737$ (atomic ratio) and a corrected biotite age of 412 m.y. For *JET*/2 the corresponding figures were 1·04, 0·732 and 429 m.y. This latter apparently discrepant age may be attributable to lack of uniformity of composition in sample *JET*/2. It was not possible to make the whole-rock determinations on exactly the same sample from which the biotites had been separated.

The data support 408 ± 7 m.y. as the date of metamorphism of the hornfelses, which on the simplest interpretation would be the date of emplacement of the granite. However, a long period of cooling would mean that these ages were younger than the date of emplacement. Alternatively, they could be the result of a post-hornfelsing thermal event in the history of the rocks. In the absence of evidence in support of the latter two possibilities we shall, for the present, consider the simplest interpretation to be the correct one.

Isotopic dating of a magmatic episode is of greatest value when the age of the magmatism is known relative to other events comprising the geological history of an area. In discussing the relative age of the acid magmatism represented by the Tan-y-grisiau intrusion, reference should be made to the following events in the structural evolution of North Wales: emplacement of basic magma (as represented by ophitic augite-dolerite sills and dykes); the impression of the regional cleavage(s); folding; faulting and crushing; and mineralization. A brief summary is given here of the available information which is relevant to such a discussion.

The Cambrian and Ordovician strata of Caernarvonshire and Merionethshire have been intruded by an immense bulk of basic magma in the form of dykes and sills[8], the majority of which are ophitic augite-dolerites. Although many basic intrusions of Ordovician age are known to occur, for example the intrusive sheets of Cader Idris (pre-Upper Ordovician)[14], most of the dykes and sills are thought to be late Caledonian[8,9]. Recent field-work has shown that the Tan-y-grisiau intrusion is cut by several of such dykes, and, therefore, pre-dates the episode of basic magmatism represented by them. Some of these dykes have been affected by subsequent shear movements while others are only slightly sheared. (A whole-rock potassium–argon determination has been made on such a dyke, see Table 1.) The previously held view[8] that the Tan-y-grisiau granite "must be appreciably younger than the dolerites" has to be reconsidered. If there were but one episode of late Caledonian injection of basic magma (namely, that which produced the dykes cutting the granite), then this view is incorrect. If more than one phase is envisaged, then the Tan-y-grisiau intrusion pre-dates at least one of them. It is interesting to note that Caledonian microgranophyres cut by late Caledonian ophitic dolerites have been reported from the Moel Hebog area[9]. The recognition of post-granite dolerite injection means that Read's[1] catalogue of events for the "non-metamorphic Caledonides" must be modified. Further modifications seem likely in the light of recent discussion[4].

There is no general agreement regarding the age of the late Caledonian dolerites relative to the impression of the regional cleavage. Both pre-cleavage[6,9,14,15] and post-cleavage[7,16,17] ophitic dolerites have been described from Caernarvonshire and Merionethshire. Consequently, it is not feasible to establish the date of emplacement of the Tan-y-grisiau intrusion relative to the impression of the regional cleavage by reference to dolerite/cleavage age relations. Furthermore, the recognition of polyphase folding in the Caledonides of North Wales[18], each phase accompanied by the development of cleavage, underlines the need for restraint in interpreting records of cleavage/dolerite age relations until the chronology of the regional structure has been fully determined. Preliminary work by C. T. Harper at Oxford (personal communication) suggests that the cleavage associated with F_1 folding was impressed 415 m.y. ago. This compares with an average age of 410 ± 10 m.y. quoted for a cleavage event which affected rocks in Anglesey and Arvon[4].

More direct evidence concerning the date of emplacement of the intrusion has been noted by several authors. It has been tentatively suggested[5] that emplacement post-dated the cleaving of the surrounding Tremadoc rocks, as "angular cleaved fragments" of the latter were said to lie in offshoots from the intrusion. However, an examination (by J. E. T.) of localities where such fragments show bedding and cleavage suggests that the cleavage may well be related to pre-intrusion faulting and not to the regional cleavage. In the spotted Tremadoc slates of the south-west part of the Tan-y-grisiau aureole the spots are said to have grown in slate which was already cleaved[7], implying that the intrusion is younger than the regional cleavage. The occurrence of distorted fossils in massive hornstones close to the margin of the intrusion has been cited in support of this view[17]. However, observations on spotted rocks near the margin of the granite suggest that the intrusion pre-dates the regional cleavage[20]. More work is obviously needed to resolve these conflicting views.

The date of emplacement of the granite relative to the regional thrusting, which produced the zone of shear disturbances running from the Tremadoc area into Deudraeth, has been demonstrated in the area a mile and a half south-west of the main outcrop of the granite[7]. Here the spotted aureole rocks have been disrupted in a zone of minor thrusting which is later than the formation of the spots. Hence the thrusting post-dates the emplacement of the intrusion. This has been confirmed by observations made in an area a quarter of a mile south of the granite margin[20]. It has been stated that the augite-dolerite sills of Deudraeth post-date the regional thrusting[7]. If so, they must post-date the Tan-y-grisiau intrusion and confirm the observation that there was injection of basic magma later than the acid magmatism which produced the Tan-y-grisiau mass.

Research in the Aberglaslyn area[10] has shown that an inferred concealed intrusion "produced local thermal metamorphism and tourmalinization of the early Caradoc sediments in post-Llarnagian and pre-Longvillian times". If, as Fearnsides[17] and Shackleton[9] have suggested, this thermal metamorphism is attributable to a hidden extension of the Tan-y-grisiau granite, then the intrusion is of Caradocian age, that is of the same general age as the intrusive rhyolites of Moel Hebog[9]. Indeed, Beavon[10] has suggested that the Tan-y-grisiau intrusion "is a sub-volcanic granophyre related to the Snowdon Volcanic Series, rather than a Caledonian 'granite'". However, there is no direct evidence for relating the Aberglaslyn thermal metamorphism to the Tan-y-grisiau intrusion. Dating of the Bwich-y-Cywion intrusion would be of interest for comparison.

Until recently the mineralization associated with the Cambrian and Ordovician rocks of the Harlech Dome was thought to be of either Ordovician[21] or post-Carboniferous[22]

age, although part of it has been regarded as Caledonian[23]. Moorbath[24], however, on the basis of investigations of lead isotope abundance, suggested a probable Silurian age for the mineralization (mean model age of 430 ± 40 m.y.). If the lead dates are accepted the Tan-y-grisiau intrusion post-dates the mineralization.

The data given in Tables 1 and 2 suggest that the age of the Tan-y-grisiau intrusion is slightly, but not significantly, greater than the ages of the "Caledonian Newer Granites" given by Lambert and Mills[25]. The statement of Fitch *et al.*[2] that the principal Caledonian magmatism in North Wales occurred some 400–420 million years ago is supported by the data presented here. Although Beavon's contention that the age of the intrusion is Caradocian[10] cannot be conclusively refuted, the possibility of a late Silurian age must still be borne in mind, especially as a minimum age of 445 m.y. has recently been recorded for alleged Lower Caradocian volcanic rocks in Scotland[26].

The single apparent age of 314 ± 9 m.y. for the dolerite is anomalous and, since the rock is slightly sheared, is possibly the result of argon loss. However, it does confirm the view, based on the absence of olivine in the rock, that the dykes are unrelated to the early Tertiary dykes of Snowdonia.

Our thanks are due to Prof. P. Allen, Dr. R. St J. Lambert and Dr. A. Lees for their comments at various stages in the preparation of the manuscript, and to Mr C. T. Harper for permission to quote unpublished data.

STEREOCHEMICAL RELATIONSHIP BETWEEN CODING TRIPLETS AND AMINO-ACIDS

By Dr S. R. PELC and Miss M. G. E. WELTON
Medical Research Council Biophysics Research Unit, 26-29 Drury Lane, London, W.C.2

BASED on the genetic code as published by Nirenberg *et al.*[1], the following correlations between codons and amino-acids were deduced[2]: the amino-acids with hydrocarbon residues have U (uridine) or C (cytosine) as the second base, those with branched methyl groups have U as the second base; the basic and acidic amino-acids have A (adenine) or G (guanine) as the second base; the aromatic amino-acids and amino-acids derived from a common organic acid are grouped together; a simple structural change in an amino-acid is accompanied by a change of one base only, such that 16 out of 20 amino-acids are interconnected (Fig. 1); if the third base in a triplet influences the coding, it does so only by being either a purine or a pyrimidine. It seems unlikely that such a logical arrangement could have arisen by chance, and it was suggested that a structural relationship between coding triplets and amino-acids exists. Similar suggestions were made by Nirenberg and his collaborators[1], Weinstein[3] and Woese[4].

The hypothesis of a stereochemical relationship between nucleotide triplets and amino-acids was tested by constructing models: this article reports some results of this investigation.

Models were built using Courtaulds space-filling components in the usual way. Triplets were made up as if they were part of an RNA-chain, comprising bases, ribose sugar and phosphate bonds in the 3′-5′ sequence. Full flexibility of the RNA within the limits given by the models was assumed. Amino-acid molecules were assembled separately, and then fitted into the triplets by means of hydrogen bonds, stacking bonds and covalent bonds. Hydrogen bonds were only accepted when they were within the distances and angles defined by the components. Stacking of the heterocyclic structures was used when they were in contact or nearly so, and when they overlapped to within approximately 2 Å. Amino-acids with hydrocarbon residues possess no sites for the formation of hydrogen bonds on the hydrophobic residue. It was assumed that by removing hydrogen from a CH_3 group on the residue and from a base, a covalent bond between residue and base could be formed. For example, after the bonding of a terminal methyl group on leucine to uracil in this way, uracil resembles thymine. Methyl bonding is referred to in more detail in the discussion.

Possible bonds to the ribose sugar or phosphate link were not used. The —OH group of the carboxyl group

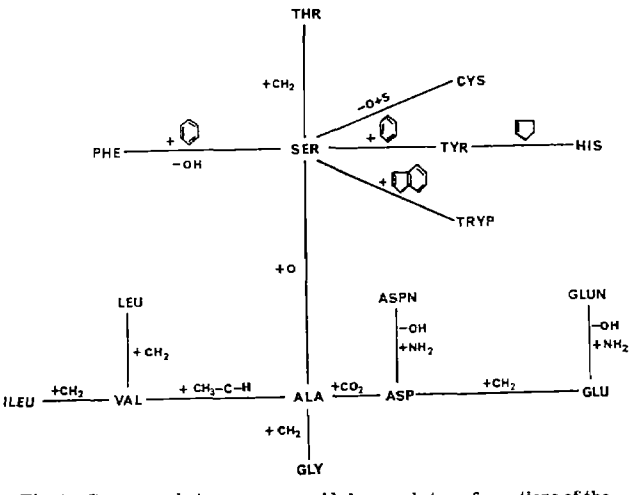

Fig. 1 Connexion between amino-acids by simple transformations of the genetic code. Each line marks a change in the structure of an amino-acid accompanied by a change of one letter of the code. For example, the structural difference between Gly (GGU) and Ala (GCU) is due to one CH_2 group. Note that biochemical relationships are different

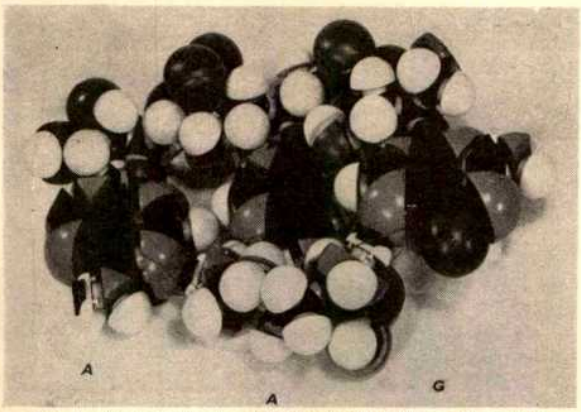

Fig. 2. Photograph of model of lysine fitted to model of AAG

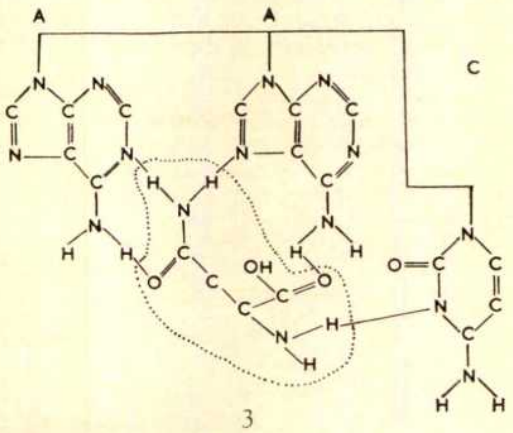
on the head of the amino-acid was left free, since it is known that this provides the link with the *t*RNA during transfer as well as participating in the peptide linkage.

We started with the assumption that the specificity of the third base might be low because it codes for a part common to all amino-acid molecules, namely, the $H_2N.CH.COOH$ group; the residue was then fitted to the first and second bases. An assembly was considered satisfactory when at least four possible bonds, of which at least two must be with the residue, could be effected without strain and without undue distortion of the triplets. The head of an amino-acid can always be fitted with hydrogen bonds to one or two bases. To provide specificity additional bonds to the residue are required.

In the following examples of amino-acids fitted into triplets, the diagrammatic representation of the arrangement is distorted due to the transfer of a three-dimensional pattern to two dimensions; in the models all bonds are at permissible angles and distances.

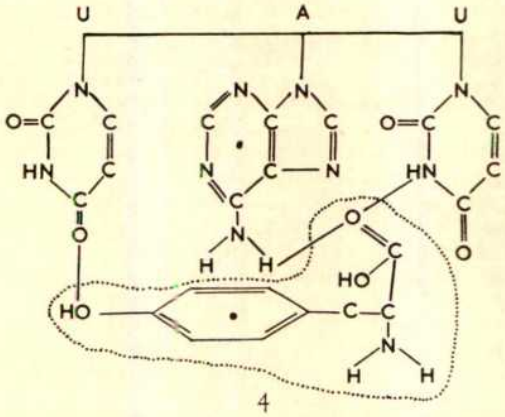
Amino-acids with acidic or basic residues could be fitted by hydrogen bonds alone to their codons in a satisfactory manner. The fitting of other amino-acids was more complicated.

Lysine. Forms four hydrogen bonds with its codons AAG (Fig. 2) and AAA. The first two bases AA— are planar, with the third base stacked above the second.



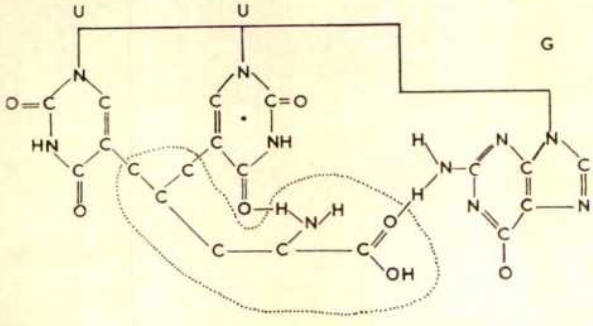
Asparagine. Can form five hydrogen bonds with its codons, AAU (Fig. 3), and AAC.

Tyrosine. Can be fitted into UAU (Fig. 4) and UAC using three hydrogen bonds and one stacking bond. The amino-acid lies above the central base (A), the three bases lying approximately in the same plane.



Leucine. Since no sites for hydrogen bonding are available on the residue, this can be fitted with hydrogen bonds to the head only, and by shielding the hydrophobic residue of the amino-acid in a fairly satisfactory way to CUA and CUC and less satisfactorily to UUG. Leucine can also be fitted in ways which are strained or otherwise unsatisfactory to UUC and UUU. This shielding of the residue using Courtaulds models is a very subjective criterion of a fit.

If it is assumed that terminal methyl groups can bond to bases (Fig. 5), leucine can be fitted in a planar arrangement to UUG, CUG, CUU, CUC, CUA and UUA. Thus leucine fits the triplets of the genetic code in a manner which can be clearly defined.



Methionine. Will form a planar arrangement with four hydrogen bonds, two of which are to the sulphur atom with AUG and AUA. If it is assumed that terminal methyl groups can bond to a base (see later) methionine

will form four hydrogen bonds and one such methyl bond, the methyl bond being to the second base, with AUA (Fig. 6) and in a strained model with AUG.

Other amino-acids. The results of attempts to build models of the possible combinations of other amino-acids to triplets assigned to them in the genetic code are shown in Table 1. A more extensive investigation into other possible fits and possible specificity of the system will be reported separately.

If utilizing the methyl bond is accepted, only four combinations of codon and amino-acid cannot be effected, three of which involve uncertain placings in the code, namely, ser-UCA, AGU, AGC and arg-CGU (ref. 5). Combinations regarded as strained are doubtful since the parameters of the components used cannot be assumed to represent the dimensions of molecules with perfect accuracy. There is thus good, though not perfect, agreement with the genetic code, so far as the criterion for a fit is concerned.

Except for the smallest amino-acids all satisfactory models were built by fitting first the $H_2N.CH.COOH$ group, the head of the amino-acid, to the third base of the triplet; attempts to do otherwise ended in failure. Since, as is shown in Table 1, most amino-acids can be successfully fitted to the respective codons, it can be concluded that this is the correct way to approach the problem. So far as these models are concerned the angle sub-tended between the base and the rest of the RNA forms the difference between purines and pyrimidines in aligning the residue for bonding to the other bases. It can be concluded that the limited specificity of the third base can be explained by these findings.

The residue can be fitted to the other bases by hydrogen bonds, stacking or by means of a terminal methyl group. The restraints within a system are therefore given (*a*) by the number of possible bonds which is a function of suitable configurations on the amino-acid residue and on the bases, and (*b*) by the spatial relationship of the atoms suitable to form the bonds. The substitution of pyrimidine for purine in the third base does not significantly change the number of possible bonds between the amino-acid and the bases, but the spatial relationship can be altered in such a way that the amino-acid will not successfully fit some combinations.

No sites for possible hydrogen bonds are available on the residues of some amino-acids. In a few instances good fits were obtained when the bases formed a cavity enveloping the residue and protecting it from contact with water, but the arrangement cannot be considered satisfactory until forces to effect and to stabilize such a system are defined. It was assumed that terminal methyl groups on an amino-acid residue could be bonded to a base. The formation of such bonds, which change bases in such a way that they resemble methylated bases, would require an enzyme. Methylated bases in *t*RNA and the required enzymes (*t*RNA methylases) have been found[6,7]; it seems possible that the function of these enzymes is connected with the assembly of complexes of amino-acids and RNA. Utilizing this principle, more satisfactory assemblies were constructed.

The small amino-acids, glycine and alanine, follow a genuine double code because only two bases are bound to the amino-acid; other amino-acids, such as threonine, follow a code which is only double in appearance, since all three bases are bound to the amino-acid, but the third base is non-specific because the difference in angle between purine and pyrimidine is insufficient to make attachment impossible.

It can be concluded that it is possible to fit amino-acids stereochemically to their codons and that the low specificity of the third base can be explained by our findings.

SPECIFICITY OF THE STEREOCHEMICAL RELATIONSHIP BETWEEN RIBONUCLEIC ACID-TRIPLETS AND AMINO-ACIDS

By Miss M. G. E. WELTON and Dr. S. R. PELC

Medical Research Council Biophysics Research Unit, 26-29 Drury Lane, London, W.C.2

In the preceding article the stereochemical fitting of amino-acids to the codons ascribed to them by Nirenberg *et al.*[1] was reported. The possible existence of structural relationships between amino-acids and their coding triplets had already been suggested by Nirenberg *et al.*[1], Weinstein[2] and Woese[3], and the correlations between amino-acids and their coding bases have been established by Pelc[4].

We used Courtaulds space-filling components to construct amino-acid molecules and sections of RNA chain complete with bases. The amino-acids were then stereochemically fitted to the base triplets. Except for glycine and alanine, the two smallest amino-acids, the head of the amino-acid, $NH_2.CH.COOH$, is always bonded to the third base, and the similarity of the hydrogen bonds used explains the low specificity of the third base. In fitting the amino-acids to their codons we realized that changing a purine for a pyrimidine, or vice versa, as third base, did not alter the possible bonds, but did alter the alignment of the amino-acid with the other two bases. In fact the bonds made with the third base orientate the amino-acid relative to the RNA chain. The amino-acid is then fitted to the other two bases using hydrogen bonds, stacking bonds, and methyl bonds (see preceding article for further details).

Models of 90 per cent of the codon-amino-acid complexes required by the genetic code could be achieved without introducing undue strain. The present article reports

Table 1. SURVEY OF AMINO-ACIDS FITTED TO TRIPLETS

AA	Codons	Other good fits	Strained	Imposs.	Not accounted

% of 640	5·0 fitted, 0·6 not fitted	3·0	10·0	62·0	19·3
% of 517	6·2 fitted, 0·8 not fitted	3·7	14·0	76·0	

Total No. of triplets for 10 amino-acids is 640, of which 517 were tried.
leu 2 and met 2: models were constructed utilizing methyl bonds. leu 1 and met 1: constructed without methyl bonds. Codons: as assigned by Nirenberg *et al.* (ref. 1). Codons marked with an asterisk (*) could not be fitted; all others were good fits with no strain. Strained and impossible: some uncertainty is attached to these placings since, if standards of accuracy are relaxed, some combinations which we deemed impossible might be regarded as strained or even good fits; furthermore, the limitations imposed by the standardized sizes and angles of the components have to be borne in mind.
Not accounted: the number of combinations that were not tried at all or not sufficiently tried to justify assignment. Per cent of 640: percentages relating to all possible combinations; since there are 64 triplets and 10 amino-acids were examined in sufficient detail, there exist 640 possibilities. Per cent of 517: percentages relating to all combinations which were examined, that is (640—not accounted). Figures with question mark (?) are uncertain placements.
All figures in parentheses were disregarded for statistical evaluation—leu 1 and met 1 because the use of methyl bonds gives better agreement with experiments, the aromatic amino-acids his and tyr because of the uncertain specificity of the stacking bonds.

results of further investigations on the specificity of these stereochemical fits. For this purpose a triplet was built up and the head of the amino-acid was bonded to the third base. Fitting of the amino-acid to the first and second bases was then attempted. The head of an amino-acid can always be fitted to one or two bases and will make at least two hydrogen bonds with them; this bonding is therefore non-specific. An assembly was considered satisfactory when the residue formed at least two bonds with the triplet so that, including the bonds to the head, a minimum of four bonds between amino-acid and triplet is achieved without undue strain or distortion of the molecules. The larger amino-acids have more possible binding sites.

Triplets marked with an asterisk (*) are those found in the genetic code[1].

Asparagine. Can form five hydrogen bonds with a suitable triplet. It was found that neither a pyrimidine nor G can be the second letter; the last letter is always a pyrimidine. U, and probably G, cannot be the first letter. Satisfactory arrangements with five hydrogen bonds can be formed with AAU*, AAC*, CAC and CAU.

If the hydroxyl group is utilized for hydrogen bonding, asparagine can also be fitted to the following triplets: AGC, AGU, CGC, CGU and AGA. We consider such an arrangement unsuitable because then the —OH group would not be available for peptide forming or enzyme–ATP binding.

Methionine. Will form a planar arrangement with four hydrogen bonds, two of which are to the sulphur atom with AUG* and AUA*. If it is assumed that terminal methyl groups can bond to a base (see preceding article and later in this article) methionine will form four hydrogen bonds and one such methyl bond in a satisfactory arrangement with AUA* and in a strained configuration with AUG* and AUC.

Leucine. Since no sites for hydrogen bonding are available on the residue, this can be fitted with hydrogen bonds to the head only, and by shielding of the hydrocarbon residue of the amino-acid by the bases, to CUA* and CUC* which are satisfactory, and to UUG* which is less so. Leucine can also be fitted in ways which are strained or otherwise unsatisfactory to GUG, UUC and UUU. It can be fitted neither to CUU*, CUG*, UUA*, nor to any triplets with CC— as the first two bases, or triplets with G or A as the second base. However, these fits involving shielding of the residue tend to be very subjective.

If it is assumed that terminal methyl groups can bond to bases, leucine can be fitted in a planar arrangement to UUG*, CUG*, CUA*, CUU*, CUC*, UUA*, UUU and UUC. It will be seen that in this case the fitting of leucine agrees with the genetic code and, since leucine is bound to ribosomes with UUU and UUC as 'messenger' in biochemical experiments, with the experimental evidence as well.

Other amino-acids. The results of attempts to build models of the possible combination of other amino-acids to triplets are shown in Table 1.

Out of ten amino-acids (Table 1), if methyl bonding to the base can be assumed, methionine is specific and leucine agrees with the incorporation experiments, although not entirely with the genetic code. Of the nineteen combinations shown in the column 'Other good fits', six are to be regarded as possible if incorporation in biochemical experiments, rather than inclusion in the code, is regarded as a criterion. The combinations mentioned in the column 'strained fits' have to be regarded as doubtful since the components used cannot be assumed to represent the parameters of the molecules with perfect accuracy.

The ten amino-acids examined in detail could *a priori* have been expected to fit into $10 \times 64 = 640$ possible triplets. Of these 517 were tested and it was found that 395 plus 67 strained ones, or 76·0 per cent plus 14 per cent, respectively, could not be fitted. Of the 8 per cent which could be fitted, approximately 5 per cent agree with the genetic code of Nirenberg *et al.*[1]. In Table 2 are listed seventeen triplets which stimulated incorporation of amino-acids but were not accepted for the genetic code by Nirenberg and his collaborators[1,5]. Of thirteen that were tried, eleven, that is, 85 per cent, could be fitted, which cannot be due to chance since on the large sample 90 per cent could not be fitted.

Our results indicate a high degree of specificity in bonding amino-acids to codons, very good agreement with the experimental findings of Nirenberg and his collaborators, and good though not perfect agreement with the genetic code. The placing of arginine and serine in the genetic code is not certain[6]. There is thus the possibility of even better agreement between the models and the genetic code.

The way in which our model system can explain the limited specificity of the third base has already been discussed in the preceding article. For example, lysine will fit equally well into AAA* or AAG*, but not AAU or AAC, the pyrimidine molecules being too small to effect the necessary bonds in this case as third base.

It can be concluded from the results in the preceding article that amino-acids can be fitted to codons and from the results summarized in Table 1 that the system provides some specificity. In view of the almost full specificity of threonine and some impossible fits, a correlation between amino-acid and anti-codon can be excluded. No reliable criteria for stacking bonds are available, and therefore the high degree of specificity of the fits for histidine and tyrosine, based on an overlap of the heterocyclic rings within 2 Å, can only be provisionally accepted.

The specificity of our system is determined by three factors, the success of fitting of amino-acids into their codons, the possibility of fitting amino-acids to triplets other than codons and the impossible fits (Table 1). There is good correlation between the triplets listed under the heading 'Other good fits' and the experiments on the stimulation of amino-acid incorporation by synthetic

*m*RNA (Table 2). The biological significance of these combinations ultimately depends on the possibility and number of 'mistakes' in an amino-acid sequence in a given protein synthesized *in vivo*. Little evidence on this point is available and it would seem prudent to defer discussion. The combinations listed as impossible in Table 1 form the majority of all possibilities. A few of them might ultimately be found to be possible, especially if different rules for building models are accepted. However, we feel sure that in most cases no such possibility exists, since the relevant parameters are too different. A minor shift from impossible to strained or even good fits would not materially affect the conclusion that the system is of limited specificity and that the degree of specificity is very similar to that of the relevant biochemical experiments.

In view of the good correlation with experimental findings and the fact that Ingram and Sullivan[7] observed that some amino-acids were attached to *s*RNA by bonds other than amino-acyl ribose bonds, it seems unlikely that such complexes are not used in biological systems. This point is also supported by Weinstein's[2] argument that mutations of the genetic code would be expected in the absence of structural correlations between amino-acids and triplets; since the code is universal, that is, non-mutated, there must be a relationship which is still of importance.

In 1958 Crick[8], under the assumption that RNA could not form 'cavities' to accept amino-acids, suggested the existence of an adaptor system for the recognition of codon and amino-acid. In the combination of adaptive enzyme and *t*RNA, this adaptor was found. Two possibilities of utilizing the findings reported here for the system of protein synthesis can be visualized. (*a*) With the help of an adaptive enzyme an amino-acid molecule is fitted to, or recognized by, the codon on the *t*RNA and the anti-codon on the same later recognizes the codon on the *m*RNA. (*b*) The adaptor system is used to insert an amino-acid molecule into the respective codon on the *m*RNA and protein synthesis then proceeds along the *m*RNA attached to a ribosome. The former suggestion does not lead to any major changes in the adaptor system as visualized at present (for reviews see refs. 9 and 10). In its favour also is the fact that both a codon (GCG) as well as an anti-codon (CGC) for alanine can be found in the sequence of bases determined for an alanine-*t*RNA by Holley *et al.*[11].

The known binding of amino-acid molecules to the C—C—A terminal group of *t*RNA would suggest either that the codon on the RNA only aids in recognition or that in fact the amino-acid is fitted into the codon during transfer. In all successful models listed in Table 1 the —OH of the carboxyl group was not used for bonding to the bases and is therefore available for reactions.

In favour of the second possibility (*b*) is the consideration that the resulting system of protein synthesis would be more compact since ribosome, *m*RNA and the site of addition of amino-acids to the growing peptide would be near together. Bernfield and Nirenberg[12] found that nearly 100 per cent of ^{14}C-phe-*t*RNA was bound to ribosomes charged with poly-U. Since both the trinucleotides UUU and UUC were able to stimulate incorporation of ^{14}C-phe-*t*RNA this result suggests that the affinity of the codon is for the amino-acid and not for the *t*RNA. Experiments of Chapeville *et al.*[13] showed that, if cysteine while bound to *t*RNA is changed to alanine, the amino-acid will still bond to ribosomes with poly-UG as primer. Preliminary trials have shown that alanine, as might be expected from its size, follows a double code and can be fitted to UGC, CGC, AGC, and GGC as well as to the codons beginning with GC— assigned to it. This is in agreement with the experiments of Nirenberg *et al.*[1], who found that UGC, CGC and AGC stimulate the incorporation of alanine into ribosomes. Cysteine can be fitted to UGC, UGU, CGC and CGU. There is, therefore, an overlap and some similarity in the codons, and the results of Chapeville *et al.*[13] may not be so conclusive for the role of *t*RNA in protein synthesis as has been assumed. The available evidence is clearly contradictory. It seems more likely that a coding triplet on *t*RNA aids in recognition (assumption *a*), but a more direct role of the *m*RNA should not be altogether rejected.

The evolution of the genetic code may be reflected in the stereochemical relationship reported here. The structural sequences reported in the preceding article (Fig. 1) are in some instances similar to, and in others different from, the known biochemical and biosynthetic correlations, and a clear distinction between the evolution of amino-acids as chemicals and the evolution of a genetic code must be made. Our evidence rather suggests that the two are not coincidental.

It should be emphasized that, at this stage, our ideas are tentative and that the evidence from molecular model building which we present is in itself not conclusive.

Note added in proof. Recently, Hayashi and Miura (*Nature*, **209**, 376; 1966) found that the rate of formation of phenylalanyl-*t*RNA (phenylalanine code—UUU and UUC) was strongly reduced when oligo-A was added to the reaction mixture, but only slightly reduced when oligo-U, and not affected when oligo-C, were added. Similarly, oligo-U, but not oligo-A or oligo-C, strongly reduced the rate of formation of lysyl-*t*RNA; and oligo-G and slightly oligo-C, but not oligo-U or oligo-A, reduced the formation rate of prolyl-*t*RNA. Hayashi and Miura propose that the amino-acyl synthetase recognition site on the *t*RNA is the anti-codon for the respective amino-acid. We suggest that, if the site recognizing the amino-acid is the codon (our assumption (*a*)), the results can be explained as the formation on this site of Watson–Crick pairs with the oligo-nucleotide equivalent to the anti-codon, which would render recognition impossible. The weaker effects of oligo-nucleotides equivalent to the codons may be due to distortion of the *t*RNA molecules due to pairing of oligo-nucleotide and anti-codon, or to direct competition for the amino-acid.

OPTICAL ROTATORY DISPERSION OF OLIGOADENYLIC ACIDS AND A CONSIDERATION OF THE FACTORS STABILIZING HELICAL POLYNUCLEOTIDES[1]

By Dr. A. M. MICHELSON
Institut Biologie Physico-Chimique, Paris

Dr. T. L. V. ULBRICHT
Twyford Laboratories, London, N.W.10

AND

Dr. T. R. EMERSON and R. J. SWAN
Westfield College, London, N.W.3

SOME time ago we observed that when adenylic acid (AMP), the optical rotatory dispersion of which is similar to that of adenosine[2], is combined in a dinucleotide, there is a remarkable change of the optical rotatory dispersion[3]. Whereas AMP has only a single weak Cotton effect in the region of the long wave-length absorption band (λ_{max} 260 mμ), adenylyl (3′-5′)-adenosine (ApA) exhibits two peaks (at 277 and 235 mμ) and a deep trough (at 255 mμ). To investigate this effect further, we have examined the optical rotatory dispersion of a series of oligoadenylic acids in buffered salt solutions (0·15 molar) at *p*H 4·86, 6·75 and 7·4 and 20°–25° C. The preparation and purification of the compounds are described elsewhere[4].

Fig. 1 shows the optical rotatory dispersion of AMP, ApA, an oligoadenylic acid of average chain-length 12 (A_{12}), and polyadenylic acid (poly A, average chain-length 200) in potassium fluoride solution over the 200–300 mμ range at *p*H 6·75. The molecular rotation is in terms of mean residue concentration. The biggest change in the form of the curve takes place on going from the monomer to the dimer. The main features of the optical rotatory dispersion curve of ApA have been discussed in an elegant paper by Warshaw, Bush and Tinoco[5]. These authors calculated that the interaction between the two bases in ApA leads to a splitting of the 260 mμ absorption band of each adenine by 14 mμ. The two bands produced must have Cotton effects which are of opposite sign and of approximately equal magnitude. Considering the approximations involved in the calculation, the predicted positions of the two bands (253 mμ and 267 mμ) are in reasonable agreement with the experimental cross-over points of the optical rotatory dispersion curve (247 mμ and 267 mμ). Overlap between the two Cotton effects leads to the deep trough at 255 mμ. It thus appears that the observed optical rotatory dispersion curve consists of a first positive Cotton effect (peak 277, trough 255 mμ) and a second negative Cotton effect (trough 255, peak 235 mμ). There also appears to be a third positive Cotton effect with a peak at about 224 mμ (sometimes as an inflexion on the 235 mμ peak) and a trough at about 215 mμ. (These two extrema are not always observable and the figures are approximate.)

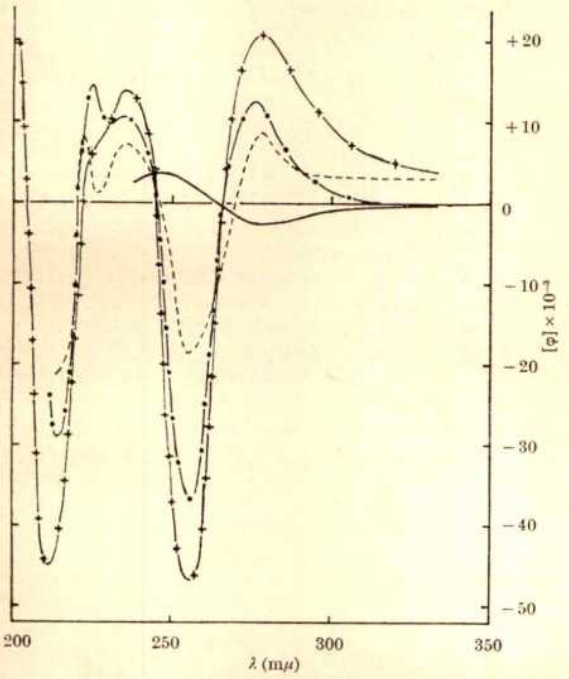

Fig. 1. Optical rotatory dispersion of AMP (———), ApA (– – – –), A_{12} (●—●) and poly A (+—+) in 0·15 M potassium fluoride, *p*H 6·75. [φ] = mean residue molecular rotation

Addition of further adenylic acid residues produces a gradual increase in base interaction which stabilizes the stacked, single-stranded form of polyadenylic acid now believed to exist at neutral *p*H[6–8]. Table 1 shows the increase in the amplitude of the first Cotton effect (first peak to first trough) with increasing chain-length. (The results at *p*H 7·4 were very similar to those at *p*H 6·75.) Investigations of circular dichroism indicate that base interaction at neutral *p*H reaches a maximum when the oligoadenylic acid chain contains about 30 residues[4]. In the case of the second Cotton effect (first trough to second peak) this gradual increase does not appear at all at *p*H 4·86, although at *p*H 6·75 it does for almost all chain-lengths.

No significant change in the position of the extrema or cross-over points with chain-length or *p*H was observed in our investigations, with one exception. This change is associated with a dramatic change in amplitude and secondary structure. Poly A at *p*H 4·86 has a trough at 251 mμ; this is significantly different from the value of 255 ± 1 mμ found in all our other measurements of this extremum. (There is a corresponding shift in the absorption maximum of poly A from 257 to 252 mμ (ref. 7).) The amplitude of the first Cotton effect at *p*H 4·86 increases gradually up to A_{12}, in a manner similar to that at neutral *p*H. However, whereas the increase in amplitude on going from A_{12} to poly A is less than 40 per cent at *p*H 6·75, it is more than 200 per cent at *p*H 4·86. This big change is undoubtedly due to a transition to the protonated, double-helical form of poly A, known to exist below *p*H 5. At *p*H 4·5 the transition appears to begin at a chain-length of seven[4]; it is clear from our results that, at *p*H 4·86, one is approaching the limiting *p*H for the stability of the double helical form, which requires a chain-length >12. The gradual increase up to A_{12}, like the increases at neutral *p*H, is interpreted as being due to a single-stranded helical form; again, the correlation is only with the first Cotton effect.

These results are in agreement with conclusions drawn from other recent studies[4–8]. In the past few years a remarkable change has taken place in theories regarding the stability of helical polynucleotides. It was originally supposed, on the basis of the Watson–Crick structure, that hydrogen bonds between the bases were the main, or indeed the only, factor responsible for the stability of the DNA double helix in aqueous solution, despite the well-

known fact that water can itself form strong hydrogen bonds with the nucleic acid bases. That the stability of DNA to heat was proportional to its GC (guanine + cytosine) content was interpreted as being due to the fact that, whereas G + C form three hydrogen bonds, adenine and thymine form only two. It soon became apparent, however, that the hyperchromic effect associated with the heat-denaturation of DNA could not be ascribed to the breaking of the hydrogen bonds between the bases[9]. A number of other results also indicated that hydrogen-bonding could not account for the stability of the DNA double helix. For example, the melting-temperature (T_m) of DNA is unchanged when all the hydrogen atoms are replaced by deuterium[10]. Moreover, the classical hydrogen-bond breaking agents, such as urea, are much less effective in denaturing DNA than are, for example, certain anions like ClO_4^- and Cl_3CCOO^-, which are hydrophobic bond breaking agents. (The concept 'hydrophobic bond' implies that the attraction of the bases for each other is greater than their attraction for water molecules, with which they are surrounded on denaturation.) Recent theoretical studies also support the concept that the main factor stabilizing helical polynucleotides is base interaction[12–14].

Crothers and Zimm[14] still assume, however, that the increase in stability with GC content is due to the extra hydrogen bond between G and C. This assumption is unnecessary. Studies of the optical rotatory dispersion of oligoribonucleotides by Tinoco's group[15] have shown that, of the four RNA bases, uracil interacts less with neighbouring bases than do adenine, cytosine and guanine. If, therefore, stability is mainly due to base interaction, one would expect that DNA with the lowest thymine content (since thymine is very similar to uracil), that is, the highest GC content, would be the most stable. If this explanation is correct, the amplitude of the first Cotton effect in DNA should increase with increasing GC content, and this has indeed been found to be so[16]. (Samejima and Yang actually found a linear correlation between GC content and the molecular rotation at the first peak of DNA. In our investigations we have preferred to use amplitude, as this eliminates errors due to base-line shifts between readings.)

It is not only the DNA double helix which is stabilized by base interaction. Oligo- and poly-nucleotides can exist in single-stranded helical forms, stabilized by base stacking, as shown by some of the papers already mentioned[4–8,15], and by a study of the optical rotatory dispersion of polycytidylic acid, which, like poly A, exists as a single-standed helix at neutral *p*H (ref. 17). The denaturation of these single-stranded structures is accompanied by a hyperchromic effect and by a reduction in optical rotation, just as is the denaturation of double helical DNA. Similar changes accompany the heat denaturation of RNA, and in the past these have been interpreted as being due to separation of double-stranded regions of the molecule[18] but, as is apparent from the foregoing, exactly the same changes can be expected on heating a single-stranded polynucleotide in which the bases are stacked in helical array as a result of base interaction. Consequently there is now considerable doubt regarding the secondary structure of RNA. It is interesting that, in the one type of soluble RNA (*s*RNA) the primary structure of which has been completely determined[19], the base sequence is such that the longest complementary sequence which could give rise to base-pairing between different parts of the chain is only five nucleotides long. Hence double-stranded regions in this molecule must be quite short or contain many imperfections in base-pairing, a conclusion which is in marked contrast to recently discussed models of *s*RNA with more than 80 per cent of base-pairing[20–22].

Note added in proof. Recent studies of the optical rotatory dispersion of *s*RNA suggest that the main factor stabilizing its secondary structure is hydrophobic bonding[23,24].

Measurements of optical rotatory dispersion were made with the Bellingham and Stanley/Bendix-Ericsson Spectropolarimeter 'Polarmatic '62'.

ROLE OF LYSOSOMES AND OF CELL MEMBRANES IN PHOTOSENSITIZATION

By Dr. A. C. ALLISON, Dr. I. A. MAGNUS and M. R. YOUNG

National Institute for Medical Research, Mill Hill, and Institute of Dermatology, St. John's Hospital for Diseases of the Skin, London

DAMAGE to cells and tissues can be produced *in vivo* or *in vitro* by the combined effects of a photosensitizing substance and light. Photosensitization occurs *in vivo* in humans or animals exposed to a variety of drugs or noxious substances, or accumulating certain metabolites as a consequence of congenital or acquired metabolic disorders. Among the compounds known to induce photosensitivity in man are phenothiazine tranquillizers, chlorothiazide diuretics, sulphanilamide and the sulphonylurea hypoglycaemic agents[1], demethylchlortetracycline[2] and coal-tar derivatives in pitch[3].

Examples of metabolic disturbances leading to photosensitization are porphyria in man and hypericism, fagopyrism, sporidesmin poisoning and tribulosis in animals[4]. Some of these effects are indirect: thus ingestion of *Tribulus terrestris* causes liver dysfunction and accumulation of phylloerythrin (from ingested chlorophyll) in peripheral blood and skin, and this is the actual photosensitizing agent[5]. A convenient model for *in vivo* photosensitization is provided by experiments in which substances such as anthracene or porphyrin are placed on or injected into the skin of human volunteers or experimental animals. Within a few minutes of exposure to light of appropriate wave-length, erythema or weal formation, associated with an itching or burning sensation, develops[3]. The action spectrum (magnitude of response at

different wave-lengths) parallels the absorption spectrum of the photosensitizer, as expected from the Grotthus–Draper law (with the exception of the furocoumarins[6]).

Isolated cells can also be destroyed by the action of photosensitizing agents and light. Detailed experiments on erythrocytes have been carried out by Blum[7]. It has also been shown that protozoa and other organisms, and mammalian cells in culture, become sensitive to light in the presence of such diverse agents as polybenzenoid hydrocarbons[8,9], neutral red[10,11], acridine orange[12], eosin[13], demethylchlortetracycline[2] and furocoumarins[14]. Blum[7] and Clare[15] have reviewed much evidence showing that both light and oxygen are necessary for photosensitization, and there is general agreement that the damage is due to photo-oxidation. Very little is known, however, about which cellular constituents are affected, although it has generally been assumed that the cell membrane is involved.

In the course of observations on the uptake of fluorescent substances by living cells[16,17], we noticed that many of the classical photosensitizing agents are concentrated in lysosomes whereas others do not enter living cells at all. Further work has shown that two types of photosensitization occur, one due to increased permeability of lysosomal membranes, with secondary effects from released lytic enzymes, and the other resulting from increased permeability of cell membranes. These two types of photosensitization differ in certain important respects, and they provide useful techniques by which selective damage to lysosomes or cell membranes can be achieved. Studies by time-lapse ciné-micrography have revealed a number of features characterizing the two types of photosensitization, and the availability of an efficient monochromator has allowed us to determine action spectra for *in vitro* photosensitization.

Cell types. Red cells were obtained from human or rabbit blood collected into ethylenediamine tetraacetate and washed three times in 0·01 M sodium phosphate-buffered saline, *p*H 7·2. Guinea-pig and rabbit spermatozoa were obtained from the epididymis and suspended in Baker's buffered sperm diluent[18]. Cultures of mouse peritoneal macrophages, monkey kidney cells and human diploid cells (*WI*-38 strain) were prepared on coverslips as previously described[19,20].

Photosensitization. Anthracene, uroporphyrin I, eosin, neutral red, rose bengal, acridine orange and vitamin A were obtained from sources already listed[17]. Highly purified samples of anthracene and uroporphyrin I, dissolved in serum and 0·1 M sodium bicarbonate respectively, were used for most of the work. Fluorescence microscopy[17] and ciné-micrography and interference microscopy with a Baker interference microscope were used to determine the intracellular fate of various substances and to follow the effects of photosensitization.

For determination of action spectra the high-intensity monochromatic light source described by Magnus *et al.*[21] was used. Light from a high-pressure xenon arc passes through a large water prism and system of quartz lenses, focusing mirrors and slits, enabling investigation of any region from 250 to 1,000 mμ. Measurements of light energy were made with a Schwartz linear vacuum thermopile with quartz window coupled to a sensitive galvanometer. Except at very short wave-lengths (340 mμ and less) coverslips with cells were illuminated within glass tubes, but outside the culture medium, to ensure sterility. The slit was adjusted so that part of the coverslip was illuminated, the remaining cells serving as one control. Other controls were provided by illumination of cells without the photosensitizing agent, or after prior exposure to the photosensitizing agent and incubation of the cells at 37° for 30 min in medium equilibrated with 95 per cent nitrogen + 5 per cent carbon dioxide.

Estimates of cell viability. A modification was developed of the eosin dye-exclusion method originally due to Schrek[22]. The technique as usually applied gives erratic results on cells other than certain tumour cells for which it was originally devised, as Black and Berenbaum[23] have recently emphasized. This is chiefly because the high concentrations of eosin present produce variable amounts of photodynamic damage unless care is taken to exclude light in the course of preparing specimens. We added 1 : 10,000 (wt. vol.) eosin to the culture medium and incubated in the dark for 10 min; cultures are then washed in medium without eosin before observation by fluorescence microscopy. Dead cells showed marked uptake of dye and fluorescence, whereas very little or no fluorescence was present in living cells. Another useful technique was incubation of cells for 30 min in the dark with euchrysine (1 : 100,000 in culture medium), washing in fresh medium and examination by fluorescence microscopy. In living cells, lysosomes fluoresce as discrete orange masses in cytoplasm, and nucleus and nucleolus green; in dead cells there is weak, diffuse green fluorescence of cytoplasm. Estimates of viability by the two methods showed good correlation.

Histochemistry. Acid phosphatase staining of unfixed cells was carried out by the Gomori technique as described elsewhere[19].

Observations on localization of photosensitizing agents. Living monkey kidney cells and macrophages incubated with non-toxic concentrations of anthracene and other polybenzenoid hydrocarbons, uroporphyrin I, vitamin A or neutral red showed localization of these compounds in lysosomes when examined by fluorescence microscopy, as described previously[17]. The identification of these organelles as lysosomes was based on the combined use of fluorescence microscopy, light microscopy and acid phosphatase staining in the same preparations. The characteristic distribution of uptake in different cell types, including spermatozoa, also supports the interpretation that lysosomes are mainly—if not exclusively—involved. Acridine orange is taken up in living cells by both lysosomes and nucleus. There was no evidence that eosin or rose bengal in the concentrations used was taken up at all by the living cells which we were investigating.

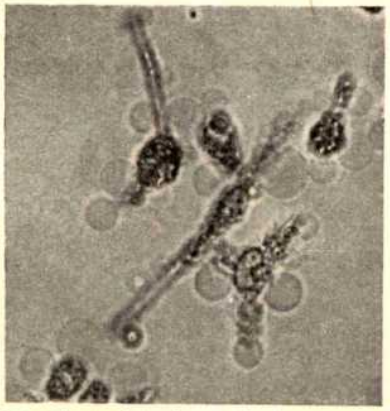
Photodynamic damage to cell membranes. This was readily demonstrated by following the haemolysis of washed mammalian erythrocytes suspended in phosphate (0·01 M)-buffered saline at *p*H 7·2 in the presence of rose bengal, uroporphyrin or anthracene and light of wavelength absorbed by these agents. More detailed observations were made by phase-contrast or interference microscopy in the presence of rose bengal (1 in 10^5) using blue-violet light from a high-pressure mercury source. After a brief interval, the cells rapidly became spherical and momentarily showed an increased optical density; a sudden drop in optical density was followed by a gradual fading to a density equivalent to that of the surrounding medium. The latter change is due to release of haemoglobin. Corresponding changes in interference colours have been recorded in colour film. These observations show that agents which normally sensitize the lysosomes (for example, porphyrin, anthracene and euchrysine) can also produce photodynamic damage to cell membranes. Further evidence in support of this view came from observations on rat and guinea-pig spermatozoa suspended in Baker's medium. When euchrysine was added (1 in 10^5) the spermatozoa were very rapidly immobilized by blue-violet light. To see how localized these effects could be, Köhler illumination giving a narrow beam of light 10μ in width was applied. It was found that light directed on to the tip of the tail immobilized only that part of the tail. These observations parallel the localized immobilization of the trypanosome flagellum by a narrow beam of light described by Walker[24]. As previously observed with trypanosomes, if the spermatozoa had been incubated with dye for some time before microscopy they were relatively resistant to photo-immobilization.

In other experiments, effects of cell-membrane photosensitization were studied in mouse macrophages with rose bengal in a culture medium lacking serum. Within a few seconds of exposure to blue light, cells were killed, with leakage of potassium, and after a short interval they showed cytoplasmic extrusion in the form of large bubbles (Fig. 1).

Photodynamic damage to lysosomes. Preliminary experiments showed that a number of cell types (HeLa, strain *A* hamster, *WI*-38 human diploid, mouse macrophages and monkey kidney cells) were sensitive to light after they had taken up neutral red, anthracene, porphyrin or acridines into their lysosomes. Detailed investigations were carried out with coverslip cultures of monkey kidney cells and mouse macrophages incubated in the dark for 1–2 h at 37° C in medium containing anthracene or uroporphyrin I (10 μg/ml.). The cells were incubated for a further 30 min in fresh medium without the photosensitizers to avoid cell membrane damage of the type described in the previous section. The photosensitizers were then detectable by fluorescence microscopy only in lysosomes. Cultures were illuminated with monochromatic light (400 mμ in the case of porphyrin and 360 mμ in the case of anthracene) for 1–90 sec, corresponding to energies of 4 to 360×10^4 μW per cm². Control cultures had no photosensitizing agent, no light, or were incubated for 30 min after uptake of the photosensitizing agents in medium without oxygen before illumination. Cultures were examined without further treatment or after incubation for 24 h at 37° C in the dark.

Only with high doses of light (60×10^4 μW per cm²) was there any immediately detectable change in the appearance of cells or loss of viability as judged by eosin staining. However, acid phosphatase staining of lysosomes of unfixed cells was detected after illumination with 12×10^4 μW per cm². Control preparations which had been illuminated in the absence of the photosensitizer showed no lysosomal staining. Since undamaged lysosomal membranes are impermeable to the β-glycerophosphate, substrate, the observations show that a very early change following illumination in the presence of this type of photosensitizing agent is increased permeability of lysosomal membranes.

After incubation for 24 h the changes were much more marked. With high doses of light nearly all the cells were destroyed and many had been shed from the coverslips into the medium. With lower doses of light, many of the cells had become rounded and ballooned, often with cytoplasmic vacuolation and pyknotic nuclei (Fig. 2).



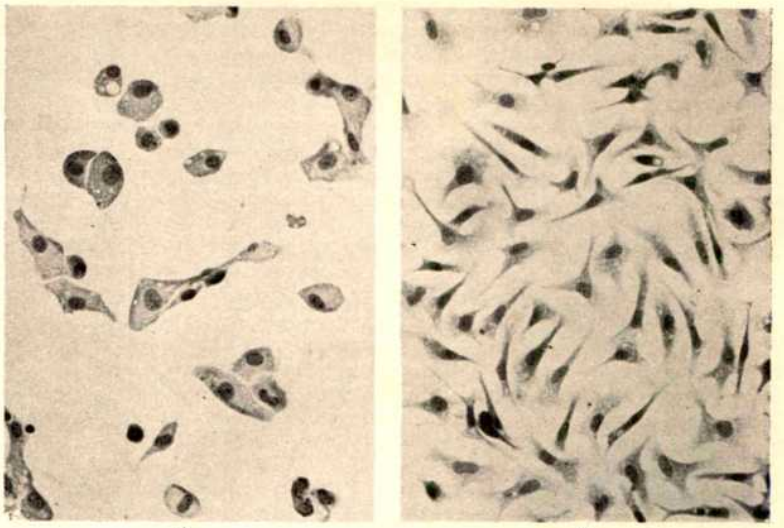


Fig. 1. Phase-contrast photomicrograph of mouse macrophages in culture 5 min after photosensitization with rose bengal, showing cytoplasmic blebs. (× *c.* 430)

A *B*

Fig. 2. *A*, Fixed and stained mouse macrophages 24 h after photosensitization with anthracene (× *c.* 245). The cells are rounded, with cytoplasmic vacuolation and dense nuclei. *B*, Control culture of macrophages (× *c.* 245)

The changes resembled those seen in cells cultured in the presence of high concentrations of oxygen, which were associated with increased permeability of lysosomes[25]. Diffuse acid phosphatase staining in cytoplasm and nuclei showed that lysosomal enzymes had, in fact, been released in the photosensitization experiments. The distinction between these two major types of photosensitization is summarized in Fig. 3.

The viabilities of cells measured at 24 h by the eosin method are plotted in Fig. 4. These show a rather flat dose-response curve which does not depart greatly from linearity. This should not, however, be interpreted as a single-photon-hit mechanism at some critical site. Fluorescence microscopy shows considerable cell-to-cell variation in the number of lysosomes containing the photosensitizer, and even if enzyme has to be released from several lysosomes to damage a cell, the probability of achieving this result might be an approximately linear function of irradiation dose. The counts of killed cells are also underestimated at high doses because of loss of uncontrolled numbers of dead cells into the medium.

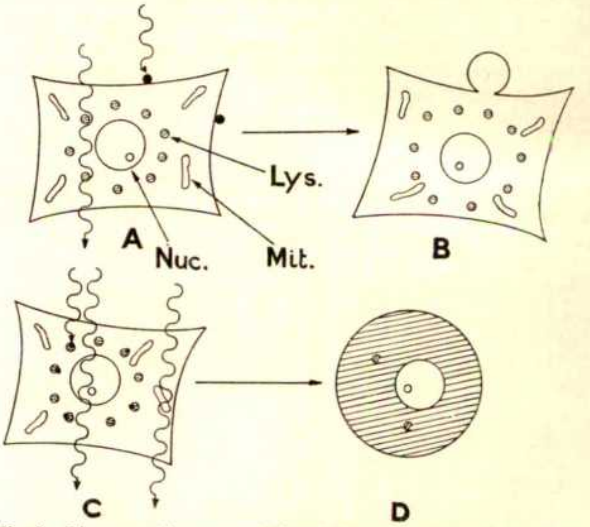

Fig. 3. Diagrammatic representation of the two major types of photosensitization. Nuc., nucleus; Mit., mitochondria; Lys., lysosomes. Some dyes, such as rose bengal, remain at the cell surface (*A*). If light of appropriate wave-length is absorbed, there is immediate photo-oxidative damage to the cell membrane, with loss of potassium and then cytoplasmic extrusion (*B*). Other substances, such as anthracene or porphyrin, are concentrated in lysosomes (*C*). If these absorb light, lysosomal enzymes escape into the cytoplasm and after some delay the cell rounds up and dies (*D*). Photons of these wave-lengths pass harmlessly through cells if no photosensitizing agent is present

These considerations have deterred us from attempting to estimate the quantum efficiency of cell killing.

When cells treated with photosensitizers were illuminated in the absence of oxygen, marked protection was seen. Similarly the same doses of light in the absence of photosensitizing agents had little or no effect. Hence, both light and oxygen are necessary for lysosomal photosensitization, as previously shown for photodynamic damage to red cells. Only cells in the path of the light beam were severely damaged, other cells on the edges of the coverslips appearing healthy. Hence the main effects were exerted on the individual cells themselves, and there was negligible accumulation of toxic materials in the culture media.

In order to obtain action spectra, macrophage cultures similarly treated with anthracene or porphyrin were illuminated with a constant dose of light (120×10^4 μW per cm^2) at different wave-lengths and the proportion of cells killed after incubation for 24 h plotted (Figs. 5 and 6). Short wave-length illumination of this intensity damages cells in the absence of a photosensitizer, as shown in the control curve *D* of Fig. 6, but above 320 mμ it was possible to show the additional effects due to anthracene photosensitization. Thus the action spectra correspond quite closely to the absorption spectra, unlike the action spectrum for anthracene wealing, which falls off below 340 mμ for reasons that will be discussed later.

Photosensitization in vivo. It will be noted that substances known to give rise to photosensitization *in vivo* (for example, porphyrin and anthracene) are of the type producing photodynamic damage to lysosomes *in vitro*. This led us to consider whether lysosomes might be involved in the hyperaemia, wealing and tissue damage associated with photosensitivity reactions in the skin. The problem is of interest because, although it is clear from action spectra that light absorption by the photosensitizing agents triggers off the responses, virtually nothing is known about the underlying mechanisms. Evidence is accumulating that lysosomes contain permeability factors that may be implicated in responses such as the Arthus reaction[26–28]. Moreover, mast cell granules (which have many of the enzymes and properties characteristic of lysosomes) contain histamine which is released when they take up stilbamidine[29]. A basic protein from polymorphonuclear lysosomes can release histamine from mast cells[26].

It therefore seemed possible that photodynamically induced permeability changes in lysosomes of dermal cells—such as endothelial cells in the papillary vasculature, or nearby mast cells—might be the primary event in photosensitization.

In order to obtain more information about vascular responses in photosensitization, we have made some observations on the living mesentery of the rat. Fluorescence microscopy revealed that about 5 min after intravenous administration of acridine orange (5 mg), the dye was present mainly in the endothelial cells of small blood vessels; these showed green fluorescence of nuclei and fine green or yellow-orange granules in the cytoplasm. The latter are almost certainly lysosomes, which have been identified in inflamed endothelial cells by acid phosphatase reactions in electron micrographs[30]. On the other hand, 15 min after intraperitoneal inoculation of acridine orange, the most prominent uptake in the mesentery was by mast cells, the granules of which fluoresced a brilliant orange.

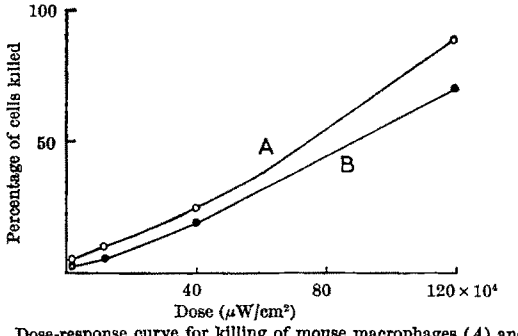

Fig. 4. Dose-response curve for killing of mouse macrophages (*A*) and monkey kidney cells (*B*) sensitized with anthracene and illuminated at 360 mμ. See text for experimental details

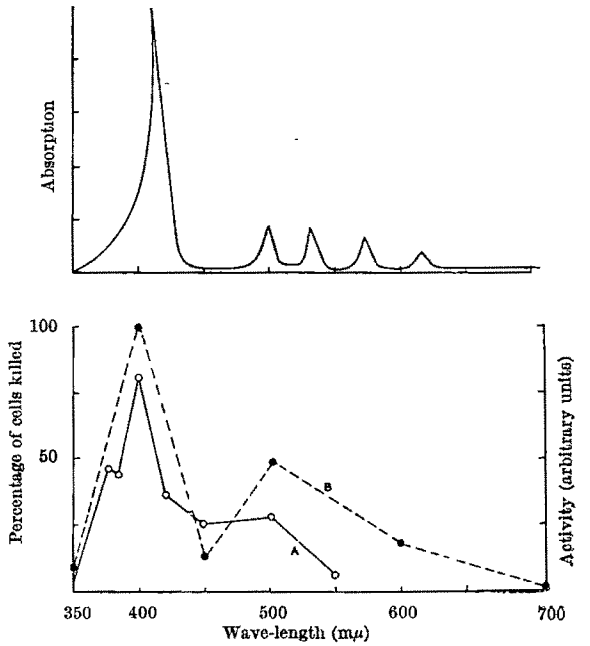

Fig. 5. *Above*, Absorption spectrum of protoporphyrin IX in dioxane (ref. 35). The absorption spectrum of uroporphyrin I is similar. *Below*, Curve *A*, action spectrum for protoporphyrin wealing in human skin (ref. 32). Curve *B*, action spectrum for killing of monkey kidney cells sensitized with uroporphyrin I

Curve *C*, action spectrum for killing of monkey kidney cells sensitized with anthracene. Curve *D*, action spectrum for killing of monkey kidney cells without any added photosensitizer. *Below*, Curve *F*, action spectrum for erythema in normal human skin (ref. 32). Curve *E* shows percentage of transmission of light through normal human epidermis (ref. 34)

There was also nuclear and some lysosomal fluorescence in mesothelial and other connective tissue cells. Thus there is uptake of photosensitizing substances by lysosomes of both endothelial and mast cells, the former being more marked (at least initially) after intravenous administration, which presumably parallels the carriage of blood-borne photosensitizer to the skin in porphyria and other conditions. Mast cell uptake is more prominent with extravascular administration, and this may parallel direct exposure of skin to anthracene or other photosensitizing substances.

Having established the lysosomal location of the photosensitizing substances, we examined the effects of light on the mesentery of the rat viewed with the Leitz 'Ultropak' microscope. Using the frog's tongue, Castellani and his colleagues[31] were able to show that, shortly after intravenous injection of relatively high doses of haematoporphyrin, exposure to light leads to stasis of blood, aggregation of cells, intravascular haemolysis and irreversible damage. We have obtained similar results in the rat mesentery after intravenous injection of uroporphyrin I or acridine orange (5 mg with prolonged illumination for 5 min or more). If pontamine sky blue (0·2 ml. of a 5 per cent solution in saline) was injected intravenously 5 min after acridine orange (5 mg) exposure of the mesentery to a narrow beam of blue light from a carbon arc produced within a few minutes localized vasodilatation and blueing; this did not occur if the acridine was omitted.

Comparable experiments were then carried out in the skin of the guinea-pig. Male albino guinea-pigs (250 g) had their flanks closely clipped and 0·1 ml. of a solution containing 100 μg uroporphyrin I was injected intradermally. Two hours later 0·5 ml. of 5 per cent pontamine sky blue was injected intravenously, and the skin illuminated for 2 min from a carbon arc with heat-absorbing filters. Intense blueing occurred within 2 min around the site of injection of porphyrin followed by illumination; later a weal developed at the site. Injection of porphyrin without illumination, or illumination at another site, had no such effect. This provides a convenient animal system for study of photosensitivity and the effects of drugs on the reaction.

It thus seems that there are two stages in the photosensitization response: first, vasodilatation and increased vascular permeability, which could give rise to erythema and wealing, and secondly, with high concentrations of the photosensitizer, haemolysis, vascular obstruction, haemorrhage and irreversible damage. The first change parallels the relatively mild photosensitization seen in experiments on human skin of the type already mentioned, and also in the common form of erythropoietic porphyria, that is, the so-called erythropoietic protoporphyria[32]. Experimental lesions show only trivial inflammatory changes histologically, but in the natural lesions of porphyria, cutanea tarda changes in the capillary walls occur. In erythropoietic porphyria similar abnormalities, with deposition of periodic-acid–Schiff- and fat-staining material, are found. The more severe reaction we have observed brings to mind the haemolysis and marked histological abnormalities in the rare Gunther's disease.

These observations are consistent with arguments previously summarized by Magnus[32] that photosensitization *in vivo* is due to effects close to the base of the epidermis rather than in the epidermis itself. The rapid onset of erythema following exposure to light suggests the release of a mediator substance very close to or within the blood vessels. In the skin of porphyric subjects (at least in Gunther's disease[32]) porphyrin fluorescence is demonstrable mainly just under the epidermis in the region of the papillary, vasculature. The failure of short wave-lengths (below 330 mμ) to induce anthracene photosensitization in the skin, although they are effective *in vitro*, could be due to loss of light through scattering and absorption before it reaches the deeper layers of the skin (Fig. 5). Failure of anthracene photosensitization to occur if the blood supply is occluded before illumination suggests that oxygen is necessary for photosensitization, *in vivo* as *in vitro*.

In summary, the evidence is consistent with the interpretation that the initial event in photosensitization *in vivo* is increased permeability of lysosomes of endothelial and possibly nearby connective tissue cells, with release of one or more chemical mediators. Antihistamines sometimes reduce urticaria experimentally induced by light in porphyric subjects, so histamine may be one of the agents involved, but the general ineffectiveness of these drugs suggests that other agents are more often responsible for vasodilatation and increased vascular permeability[32]. It is also possible that substances released from lysosomes of epidermal cells, and slowly diffusing down to the papillary vasculature, play a part in the delayed erythema following sunburn or short wave-length illumination, very little of which penetrates through the epidermis (Fig. 5). Damage to lysosomes of epidermal cells by light of these wave-lengths has been demonstrated by Weissmann and Fell[33].

Our observations on photosensitization support the growing body of evidence that lysosomes play a part in early events in the inflammatory reaction. In most experimental situations it is difficult to define which responses come first and which later. In this case there is little doubt that the initial change must be in the lysosomes containing photosensitizing agents. The simplest interpretation of subsequent events would be that endothelial cells, which are flattened and curved around small blood vessels, tend to round up and withdraw their processes (compare Fig. 2); fluid and protein could then escape between cells. The availability of an experimental animal model system showing photosensitization should allow study of the underlying pharmacology.

We thank Prof. C. Rimington and Prof. C. H. Gray for samples of porphyrin, Dr. B. E. Johnson for valuable help, Mr. C. Gilchrist for technical assistance and Mr. F. Wanless for the photomicrographs.

COMPARATIVE BIOCHEMISTRY OF PHOTOSYNTHETIC PROCESSES

By PROF HOWARD GEST

Department of Zoology and Adolphus Busch III Laboratory of Molecular Biology, Washington University, St. Louis, Missouri

INVESTIGATIONS during the past 15 years have revealed important similarities in the molecular mechanisms of photosynthesis in bacteria and green plants. In both kinds of organisms, light energy is converted into chemical energy in the form of adenosine triphosphate (ATP) and cytochromes appear to participate in photochemical electron transfer. The latter is indicated, in particular, by the observation of rapid photo-induced oxidation of reduced cytochrome over a wide temperature range[1]. On the other hand, the overall metabolism of photosynthetic bacteria is clearly distinguished from that of green plants in respect of the source of net reducing power (primarily reduced pyridine nucleotide) for biosyntheses[2–4]. In green plants, water serves as the primary reductant and oxygen is evolved as a consequence. Oxygen is not produced in bacterial photosynthesis[2] and, at first glance, this suggests that the bacteria cannot use water as an electron donor. If this is so, anaerobic photosynthetic growth on carbon dioxide as the sole carbon source would obviously require an alternative donor and, indeed, such growth is observed to be dependent on the presence of substrate quantities of an 'accessory' electron donor such as hydrogen, hydrogen sulphide or thiosulphate[2]. (The absence of oxygen production in bacterial photosynthesis could, however, be rationalized by assuming that water serves as the hydrogen donor for carbon-dioxide reduction and, in doing so, yields an oxidized product (OH) which is not convertible to oxygen; the function of the accessory electron donor, then, would be to reduce the oxidized product. This notion[2] has not received experimental support and seems to be no longer accepted by most of the workers in the field.)

One of the major unresolved, and controversial, aspects of bacterial photosynthesis concerns the pathways through which electrons from accessory donors are transported in the net generation of reduced pyridine nucleotide (PNH). Several kinds of mechanisms can be envisaged. With accessory electron donors of sufficiently low redox potential, such as hydrogen, reduced pyridine nucleotide can evidently be generated through enzymatic dark reactions, as in non-photosynthetic bacteria[5,6]. Accordingly, in photosynthetic growth on carbon dioxide, together with hydrogen, the requirement for light can in principle be entirely attributed to its necessity for production of ATP by 'cyclic' light-induced phosphorylation[7,8]. This type of phosphorylation requires neither external reductants nor oxidants, and is believed to be coupled to a cyclic transfer of electrons within the photochemical system[5,9,10] (see Figs. 1 and 2).

With physiological electron donors of relatively high potential, such as succinate, light is required to effect net reduction of pyridine nucleotide[11]. According to the so-called 'non-cyclic' electron flow hypothesis, the reduction of pyridine nucleotide with such donors requires direct intervention of the photochemical system, that is, the action of light presumably results in transfer of electrons from the photochemical system to pyridine nucleotide and these are 'replaced' by electrons derived from the accessory donor (for example, succinate) by way of a dark process[8]. (In some versions of the hypothesis[12], net formation of PNH is assumed to occur by this mechanism with all accessory donors, regardless of redox potential.) In effect, this implies that one or more components of the photochemical system (for example, bacteriochlorophyll) must act as a redox carrier in the transfer of electrons from donor to acceptor. Thus, in photosynthetic growth on succinate as sole carbon source, or with other accessory electron donors of high redox potential, light is presumed to be necessary both for ATP production and for the generation of PNH by means of non-cyclic electron flow.

The light-dependent production of hydrogen from accessory donors is mechanistically represented in the non-cyclic hypothesis as resulting from a similar transfer of electrons (that is, through the photochemical system) to the hydrogenase enzyme, but a satisfactory physiological rationale for operation of an electron transfer sequence of this kind has not been advanced[8].

Non-cyclic Light-induced Phosphorylation in Plants

In addition to cyclic phosphorylation, preparations from green plants also catalyse phosphorylation coupled to light-dependent net electron transfer. This process, which involves transfer of electrons from water, can be represented by the overall equation[13]:

$$4Fd_{ox} + 2ADP + 2Pi + 2H_2O \rightarrow 4Fd_{red} + 2ATP + 4H^+ + O_2$$

where Fd_{ox} is the oxidized form of the iron protein ferredoxin; Fd_{red}, the reduced form; ADP, adenosine diphosphate; Pi, inorganic phosphate. Subsequent transport

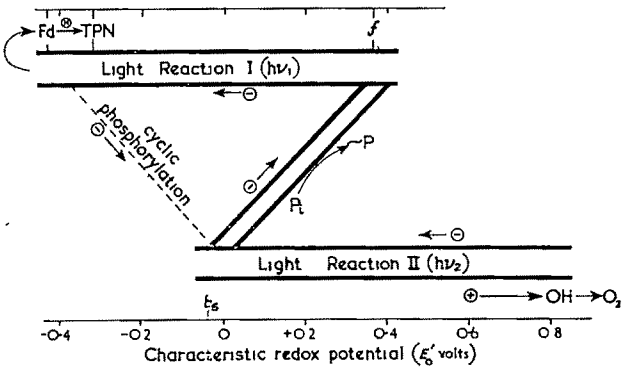

Fig. 1. Working hypothesis for light-induced electron transport and phosphorylation in green plants, after Hill (ref. 14). ⊖, Electron; ⊕, positive hole; Pi, inorganic phosphate; ~P, ATP; Fd, ferredoxin, TPN, triphosphopyridine nucleotide; *f*, cytochrome *f*; b_6, cytochrome b_6. Electrons are transported against the thermodynamic gradient in the light reactions. Light Reaction II results in formation of an electron and a positive hole; discharge of a hydroxyl ion by the positive hole forms OH, the precursor of oxygen

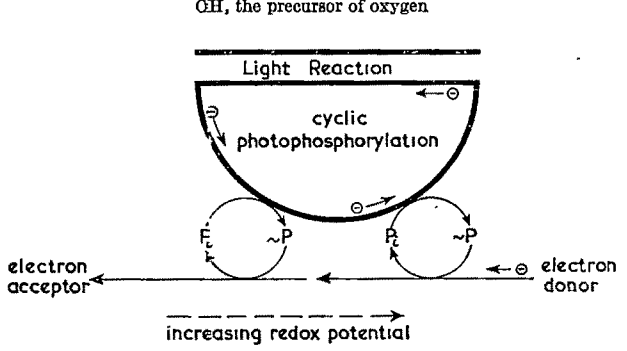

Fig. 2. A 'qualitative' scheme for reverse electron transfer driven by the cyclic phosphorylation system of photosynthetic bacteria. ⊖, Electron, Pi, inorganic phosphate; ~P, ATP or related energy-rich phosphorylated precursors. The heavy curved line represents the pathway of electron transfer in cyclic photophosphorylation; a number of catalysts, including cytochromes have been implicated. It is suggested that reverse electron transfer (horizontal long, solid arrows) may also be promoted by energy-rich non-phosphorylated precursors of ~P; note, however, that the energy coupling could equally well be expressed in terms of Mitchell's chemiosmotic hypothesis (ref. 40)

of electrons (from Fd_{red}) to pyridine nucleotide is mediated by a flavoprotein.

A working hypothesis suggested by R. Hill[14] for light-induced electron transport and phosphorylation in green plants is depicted in Fig. 1.

The scheme is based on the operation of two light reactions which transfer electrons against the thermodynamic gradient. These are connected by a thermochemical reaction (between approximately 0 V and +0·4 V), analogous to reactions characteristic of electron transfer in mitochondria. Phosphorylation coupled to net ('non-cyclic') transfer of electrons from water to Fd_{ox} is visualized as occurring in the thermochemical phase, that is, "photophosphorylation may be regarded as oxidative phosphorylation in the sense used for the mitochondrion"[14]. 'Cyclic' phosphorylation is represented as being associated with an internal cyclic transport of electrons, promoted by Light Reaction I. This light reaction involves oxidation of reduced cytochrome *f* in higher plants, or of an analogous *c*-type cytochrome in photosynthetic bacteria and algae.

There is as yet no evidence for more than one light reaction in bacterial photosynthesis. This, together with the apparent inability of the bacteria to use water as an electron donor, suggests that only Light Reaction I, or its equivalent, is operative in these organisms.

Existence of Non-cyclic Light-induced Phosphorylation in Bacterial Photosynthesis

Pigmented particles from certain photosynthetic bacteria catalyse a number of light-dependent oxidation-reduction reactions. Thus, with *Rhodospirillum rubrum* particles, light-dependent net reduction of diphosphopyridine nucleotide (DPN) is observed when either ascorbate + dichlorophenolindophenol (DCPIP)[15] or succinate[11] is used as the electron donor.

The results of an investigation[16] with *R. rubrum* particles, using ascorbate + DCPIP, have been interpreted[13,16] as demonstrating the occurrence of phosphorylation coupled to a non-cyclic light-induced flow of electrons. In the study cited, it was assumed that phosphorylation observed in the presence of antimycin *A*, a potent inhibitor of cyclic phosphorylation, must necessarily be dependent on transfer of electrons from ascorbate + DCPIP to DPN. It has been shown[17], however, that DCPIP and certain other dyes have the capacity to catalyse an antimycin-resistant electron transfer bypass in the cyclic phosphorylation mechanism. This effect of DCPIP is particularly manifest when the redox conditions are suitably 'balanced'. Over-reduction by ascorbate + DCPIP, or other electron donors, of catalysts participating in cyclic electron flow causes severe inhibition of phosphorylation[15,17–19], and this can be effectively counteracted by addition of oxidants such as DPN or fumarate. Thus, by manipulation of the experimental circumstances, light-dependent antimycin-resistant phosphorylation can be shown to have a putative 'requirement' for an electron donor system, ascorbate + DCPIP, and an electron acceptor, DPN or fumarate, even under conditions where there is no appreciable net electron transfer[17].

Since the cyclic phosphorylation system in pigmented particles isolated from photosynthetic bacteria shows great sensitivity to the redox conditions, especially in the presence of reactive oxidation-reduction dyes such as DCPIP, the interpretation of results of experiments in which exogenous reductants, oxidants and dyes are used is frequently subject to serious ambiguity. The contention[20] that the uncertainties can be avoided simply by using high concentrations of ascorbate + DCPIP as the electron donor supply is contradicted by the results of other studies[17,21].

The light-dependent oxido-reduction reaction between succinate and DPN, that is, succinate + DPN → fumarate + DPNH, can be assumed to have physiological significance and in this respect presents a more suitable system for investigation of the problem under consideration. To my knowledge, there are no published data indicating that a phosphorylation is coupled to this net electron transfer. It is significant (see later) that addition of the phosphorylation reactants (adenosine diphosphate (ADP) + inorganic phosphate (*Pi*) + Mg^{++}) causes inhibition of the oxido-reduction reaction.

In sum, it is concluded that clear-cut evidence for a ('non-cyclic') phosphorylation coupled to light-dependent net electron transfer between exogenous donors and DPN, or other acceptors, in bacterial photosynthesis has not yet been obtained.

Energy-linked Reverse Electron Transfer

Investigations with mammalian mitochondria have established that electron transfer against a thermodynamic gradient can be driven by ATP and energy-rich intermediates associated with oxidative phosphorylation[22]. This (and suggestive discussions[23–25] of photosynthetic electron transport) prompted experimental study in our laboratory[4,6,26] of the possibility that net oxido-reduction reactions dependent on, or promoted by, light in bacterial photosynthesis might also be examples of 'reverse energy-linked' electron transfer. Accordingly, the function of light would be to generate ATP, or energy-rich precursors of ATP, by means of the (anaerobic) cyclic light-induced phosphorylation mechanism; ATP or the related energy-rich intermediates would drive 'dark' transfer of hydrogen (electrons) from donor to acceptor (Fig. 2). Evidence supporting the reverse electron transfer formulation is briefly summarized:

(1) *Light-dependent formation of molecular hydrogen.* Photoproduction of hydrogen by *Rhodospirillum rubrum* requires the presence of oxidizable organic substrates, such as citric acid cycle intermediates[27]. Maximal yields of gas are observed with 'resting cells' and the quantities produced under certain conditions closely approximate those predicted on the basis of complete conversion of the organic compound to hydrogen and carbon dioxide[28], for example:

$$\underset{\text{(succinate)}}{C_4H_6O_4} + 4H_2O \rightarrow 4CO_2 + 7H_2$$

The formation of hydrogen is severely inhibited by 'uncouplers' and compounds which interfere in other ways with cyclic phosphorylation, for example, antimycin *A*, 2,4-dinitrophenol, pentachlorophenol (PCP), *m*-chlorocarbonylcyanide phenylhydrazone (*m*-CCP), *n*-butyl-3,5-diiodo-4-hydroxybenzoate (DIB), and dyes which facilitate over-reduction of catalysts of the phosphorylation system[26,28]. Addition of appropriate concentrations of such agents to illuminated cells not only abolishes hydrogen formation, but usually also induces fermentation of endogenous reserves to fatty acids, a process normally seen only during dark anaerobic metabolism[28]. That is, it appears that inhibition of cyclic phosphorylation leads to suppression of the overall photometabolism of hydrogen-producing cells.

Several lines of evidence clearly indicate that the light-dependent total conversion of succinate and other organic compounds to carbon dioxide and hydrogen occurs through operation of the citric acid cycle, coupled with a light (energy)-dependent process which in some way effects the reoxidation of reduced pyridine nucleotide by liberation of hydrogen[8,28]. The capacity to dispose of electrons in the form of hydrogen makes operation of the cycle possible under anaerobic conditions, that is, in the absence of an external terminal electron acceptor.

Rationalization of the foregoing within the framework of the non-cyclic electron flow hypothesis is difficult and, at best, requires a number of tenuous *ad hoc* assumptions. On the other hand, a reasonable interpretation of the

available data is provided by the reverse electron transfer concept which supposes that the precursor of hydrogen is reduced pyridine nucleotide, generated by the oxidative steps of the citric acid cycle[4,6,26]. Formation of hydrogen from PNH is considered to occur by reverse electron transfer (that is, with the hydrogenase system functioning as the acceptor), promoted by energy-rich intermediates associated with cyclic light-induced phosphorylation. This explanation furnishes, moreover, a plausible physiological rationale for the phenomenon of light-dependent formation of hydrogen. Thus, energy-dependent production of hydrogen can be viewed as a regulatory mechanism which aids in maintaining the pools of reduced pyridine nucleotide and ATP (or precursors) at levels consistent with the demands of the biosynthetic machinery[4,28]. In this connexion, it is worth noting that photoproduction of hydrogen from organic compounds by 'resting cells' is inhibited by addition of NH_4^+ or nitrogen gas, both of which can be readily used by photosynthetic bacteria for endergonic reductive biosynthesis of amino-acids and other cellular constituents[30].

Direct test of the assumption that PNH is the precursor of hydrogen has been hampered by failure, despite numerous attempts[31], to devise a procedure for preparing hydrogen-evolving cell-free extracts from photosynthetic bacteria. It is significant, however, that light-dependent production of hydrogen from reduced triphosphopyridine nucleotide has been observed in extracts made from the alga *Chlamydomonas eugametos*, using cells previously adapted to an anaerobic "H_2 metabolism"[32]; the effects of phosphorylation uncouplers on this activity have not yet been investigated. Relevant also to the present discussion are recent reports[33] which describe an ATP-dependent hydrogen-evolution activity in preparations derived from certain heterotrophic bacteria which, in common with photosynthetic bacteria, have the capacity to fix nitrogen. (According to Bulen, W. A., LeComte, J. R., Burns, R. C., and Hinkson, J., in *Non-Heme Iron Proteins: Role in Energy Conversion* (edit. by San Pietro, A., 261, Antioch Press, Yellow Springs, Ohio, 1965), W. S. Zaugg and W. A. Bulen have observed (unpublished experiments) ATP-dependent hydrogen-evolution by extracts from *R. rubrum*—it appears that the system is very labile.) Conceivably, in photosynthetic bacteria, a phosphorylation step might be required for the formation of a reduced compound other than PNH, that gives rise to hydrogen by way of an ordinary (dark) thermochemical conversion. Although this is considered unlikely, it may be remarked that a mechanism of this kind would, in effect, still represent a promotion of dark electron transfer by photochemically produced ATP or its congeners. (Only light-dependent formation of hydrogen is considered here; several photosynthetic micro-organisms produce hydrogen in darkness, either endogenously or from substrates such as formate and pyruvate, apparently through mechanisms similar to those characteristic of anaerobic heterotrophs[3,29].)

(2) *Light-dependent net reduction of fumarate.* Pigmented particles obtained from hydrogen-producing cells of *R. rubrum* are capable of reducing fumarate with hydrogen when catalytic quantities of certain redox carriers are added[6,26]. The relationship between the effect of light and the redox potential of the mediator can be seen in Table 1; in all instances, the oxidized form of the mediator is readily reduced by the hydrogenase (that is, with hydrogen) in darkness. As expected, mediators effective in the dark have redox potentials between, or overlapping, those of the H^+/H_2 couple ($E_0' = -0{\cdot}42$ V) and the fumarate/succinate couple ($E_0' = +0{\cdot}031$ V). With mediators having potentials in the approximate range 0 to $+0{\cdot}115$ V, the overall reaction is stimulated by light, and with carriers of still higher potential, illumination is required.

The 'light-dependent' reaction with tetramethyl-*p*-phenylenediamine (TMPD; $E_0' = +0{\cdot}26$ V) serving as mediator and the dark process catalysed by Nile blue *A* ($E_0' = -0{\cdot}119$ V) have been examined with respect to the effects of agents which uncouple phosphorylation[26]. Compounds such as PCP, *m*-CCP, and DIB inhibit the 'light-dependent' activity and, at concentrations which completely abolish the overall reaction, these agents do not affect the dark process. In our view[6,26], these observations indicate that the action of light in systems with mediators of relatively high potential is concerned with generation of energy-rich intermediates, associated with cyclic phosphorylation, which drive hydrogen (electron) transfer against an unfavourable thermodynamic gradient, that is, from reduced mediator to fumarate. Consistent with this, oligomycin—a potent inhibitor of net ATP formation by the cyclic mechanism—does not inhibit the TMPD model reaction, and, in fact, appreciably stimulates the net oxidation-reduction process. In mitochondrial oxidative phosphorylation, oligomycin is believed to prevent specifically the formation of phosphorylated intermediates from energy-rich non-phosphorylated precursors (or from ATP), but it apparently does not inhibit utilization of the postulated precursors for driving endergonic reactions[22].

(3) *Light-dependent reduction of DPN with succinate as electron donor.* Although the mechanism of this reaction is popularly discussed in terms of the non-cyclic electron flow hypothesis, it has also been suggested[4,6,26] that the oxido-reduction may occur by reverse energy-linked electron transfer, as in mitochondria. The fact that the succinate-dependent 'photoreduction' of DPN by *R. rubrum* particles is inhibited when ADP + P*i* + Mg^{++} are added[10,34] indeed suggests a competition between the oxidation-reduction reaction and the phosphorylating system for a common reactant. In sharp contrast to the behaviour of the bacterial particles, the photoreduction of pyridine nucleotide by green plant chloroplasts is greatly accelerated on addition of ADP + P*i* + Mg^{++} (ref. 35). This striking difference casts further doubt on the non-cyclic interpretation as applied to pyridine nucleotide reduction in bacterial photosynthesis.

If the reduction of DPN by *R. rubrum* particles occurs by reverse electron transport, transfer of hydrogen from succinate to the pyridine nucleotide might be detectable using tritiated succinate as substrate. Unfortunately, the results of experiments[36] designed to test this cannot be interpreted unambiguously, because the particles catalyse a hydrogen (tritium) exchange between DPNH and water. One alternative type of approach is to test the possibility that net reduction of DPN can be observed in darkness when ATP is provided. According to a recent investigation[37], this can be demonstrated using either succinate or ascorbate + TMPD as the electron donor. Furthermore, the dark reduction of DPN under these conditions is reported to be inhibited if the 'energy supply' (from ATP) is cut off by addition of oligomycin. These observations obviously argue against the non-cyclic hypothesis, but are consistent with and predictable by the reverse electron transfer formulation.

Table 1 EFFECT OF LIGHT ON REDUCTION OF FUMARATE WITH HYDROGEN BY *R. rubrum* PARTICLES; RELATIONSHIP WITH E_0' OF THE REDOX MEDIATOR*

Mediator	E_0' (V)	Light effect (requirements)
Benzyl viologen	−0·359	None
Janus green *B*	−0·256	None
Flavin mononucleotide†	−0·219	None

* After Bose and Gest (ref. 26)

† Mediator function not observed in the absence of a detergent such as deoxycholate

Two distinct general metabolic patterns can be clearly discerned in photosynthetic bacteria. I propose that these can be understood as follows[4]:

(*a*) '*Autoheterotrophic*' *pattern*. An organic compound serves as the source of carbon and through typical heterotrophic mechanisms directly provides the intermediates necessary for biosynthesis of cellular constituents; quantitatively, reduction of carbon dioxide is not necessarily a major process. ATP and its energy-rich precursors are formed by an autotrophic mechanism, that is, by light-induced cyclic phosphorylation. Reducing power is obtained by dark oxidation of organic substrate (or intermediates), and in some instances this requires an energy contribution from the phosphorylation system.

(*b*) *Autotrophic pattern*. The reductive pentose cycle operates as a major mechanism and together with other pathways enables the conversion of carbon dioxide to all cellular constituents. As in (*a*), the ATP required for these conversions, and energy for other purposes, is furnished by the cyclic phosphorylation system. The inorganic 'accessory' electron donor provides net reducing power through dark oxidation or by energy-linked reverse electron transfer.

The formation of molecular oxygen in green plant photosynthesis is considered to be a specific, and unique, consequence of the utilization of water as an electron donor for processes resulting in net production of physiological reductants. This particular means of generating reductants is absent from photosynthetic bacteria, and there is no compelling reason to assume that the alternative devices used by the bacteria to create reducing power must be 'minor variations' of the green plant mechanism. Emphasis on this important difference, its meaning and consequences, should not be construed as a cryptic argument against the notion of a general 'biochemical unity' in photosynthetic cells. Rather, I subscribe to the view[38] that recognition, and exploration of the basis, of 'biochemical diversity' is no less important for an adequate understanding of the mechanisms and evolution of specialized biochemical functions. An evolutionary transition from anaerobic photosynthesis of the bacterial type to the oxygen-producing photosynthetic mechanism of green plants would have required a significant number of alterations. The acquisition of a new and singular system, Light Reaction II, may well have played a major part in the evolution of photosynthetic cells capable of using water as a primary electron donor[4,14,39].

INVESTIGATIONS OF LEUCOCYTE KINETICS IN NORMAL AND LEUKAEMIC INDIVIDUALS BY MEANS OF SCINTILLATION COUNTING

By Dr. SEYMOUR PERRY and Dr. JOHN H. MOXLEY, III*

Medicine Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

SINCE the introduction of tritiated thymidine in 1955, it has become an important tool for the study of cellular proliferation both *in vivo* and *in vitro*[1]. It is of particular value in the investigation of *in vivo* leucocyte kinetics in normal and leukaemic individuals.

Tritiated thymidine has achieved this importance because it is a specific precursor for DNA and, since its β-emissions are of low energy, autoradiographs with high resolution can be obtained. However, the preparation and reading of autoradiographs are laborious and their interpretation extremely difficult. Accordingly, it occurred to us that liquid scintillation counting might be advantageous. This article presents some examples of the leucocyte kinetic curves after the *in vivo* administration of tritiated thymidine in normal individuals and in patients with leukaemia.

Patients admitted to the National Cancer Institute with a limited life expectancy were studied. So far three patients with localized malignancies have been given tritiated thymidine. These individuals were in good condition without evidence of malnutrition or haematopoietic disorders and were considered the 'normal' group for purposes of this study. Twelve untreated patients with

* Present address: Peter Bent Brigham Hospital, Boston, Massachusetts

chronic myelocytic leukaemia in relapse were studied together with three patients in blastic crisis and two patients with acute myeloblastic leukaemia.

Tritiated thymidine (specific activity 1·9 c./m.mole) was given intravenously at doses ranging from 40 to 100 μc./kg body-weight. At periodic intervals blood samples were obtained and processed by a method previously described[2]. The isolated leucocytes were washed in normal saline and an aliquot counted in an automatic cell counter (Coulter counter, model *B*, Coulter Electronics, Hialeah, Florida). A known number of leucocytes (about 1×10^6) was centrifuged at 2,100*g* for 10 min in a refrigerated International *PR*-2 centrifuge. The cell button was then hydrolysed and an aliquot counted in a liquid scintillation spectrometer with an efficiency for tritium of approximately 20 per cent as previously described[2]. Quenching was monitored by a channels ratio method and internal standards were used as indicated[3].

The leucocyte kinetic curves obtained were consistently reproducible within each group. There were no significant differences in two patients who were studied on two successive occasions. The amount of tritiated thymidine administered within the range used did not appear to influence either the shape of the curve or the degree of labelling. The statistical precision of the technique used will be reported separately.

Fig. 1 is a curve obtained in a 46-year-old patient with an epidermoid carcinoma of the face and illustrates the type of curve obtained in haematologically normal individuals. A low level of radioactivity is present for the first three days, but on the fifth day the level begins to rise, reaching a peak on the seventh or eighth day. As will be reported separately, the low level of activity during the first few days is due to labelled mononuclear cells, particularly lymphocytes from the thoracic duct.

In contrast to the curve obtained in normal individuals, the curve in patients with chronic myelocytic leukaemia is much more complex. Fig. 2 illustrates the results of a study in a 69-year-old woman with a white blood count of 178,500 per mm³ with the usual differential. Cytogenetic analysis of a bone-marrow aspirate revealed the presence of the *Ph*¹ chromosome. Heavy labelling is present immediately after the administration of the isotope. The level of radioactivity then declines in the first 10 h but then rises to an initial peak at 24–40 h. Another peak is present between 50 and 60 h and, finally, a third peak at 5–7 days after administration of the isotope. This last peak generally appeared a little earlier than the corresponding peak in the normal individuals.

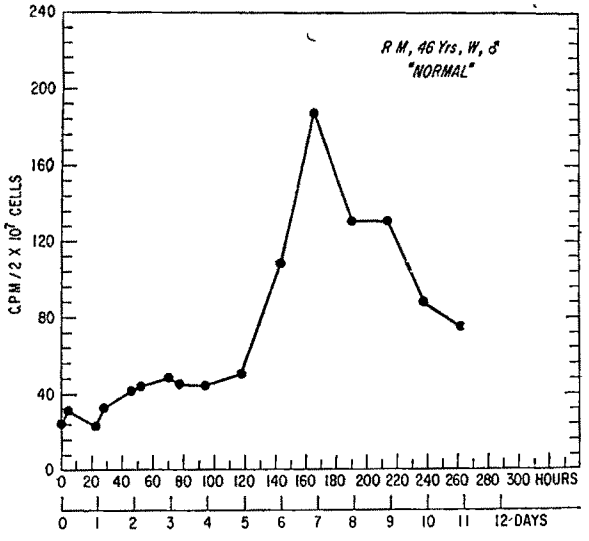

Fig. 1. Results of liquid scintillation counting of peripheral blood leucocytes from a normal individual after the administration of tritiated thymidine

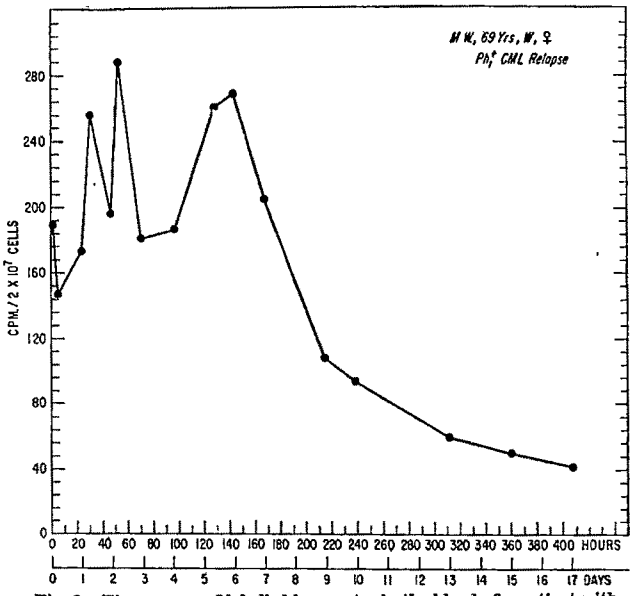

Fig. 2. Time course of labelled leucocytes in the blood of a patient with chronic myelocytic leukaemia

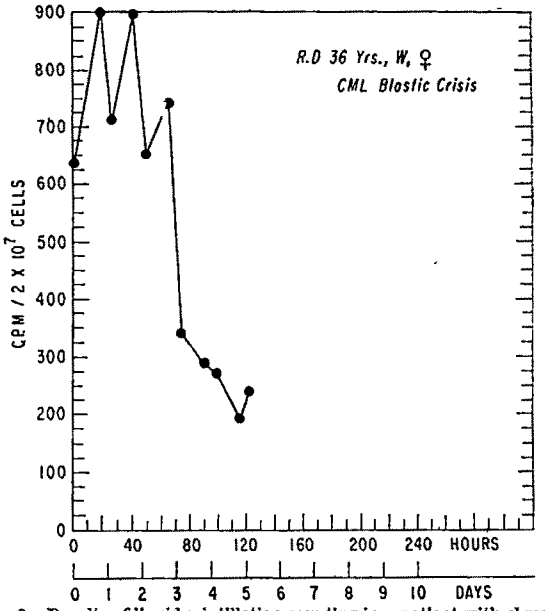

Fig. 3. Results of liquid scintillation counting in a patient with chronic myelocytic leukaemia in blastic crisis

Fig. 3 illustrates the results in a patient with chronic myelocytic leukaemia in blastic crisis. This was a 36-year-old woman with a white blood count of 4,937 per mm³ and 50 per cent blasts in the peripheral blood. Again there is an initially high level of radioactivity, rising rapidly to a double peak within 10–50 h and then declining with another small peak at 65 h. This curve is in marked contrast to that obtained in patients with chronic myelocytic leukaemia in relapse as illustrated in Fig. 2.

The leucocyte kinetic curve obtained in a patient with acute myeloblastic leukaemia is shown in Fig. 4. This was a 55-year-old man with a peripheral blood count of 81,600 per mm³, 76 per cent of the cells being blasts. Leucocyte labelling is high immediately after administration of the label, with a rapid rise to a peak between 20 and 40 h followed by another peak at 60 h. The general shape of the curve is quite similar to that found in the patients with chronic myelocytic leukaemia in blastic crisis as illustrated in Fig. 3.

The leucocyte kinetic curve obtained for a normal individual by scintillation counting is similar to the curve based on the per cent labelled cells in the peripheral blood

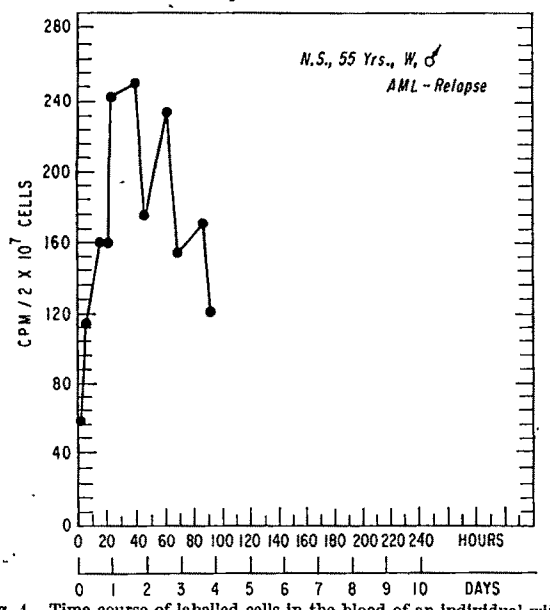

Fig. 4. Time course of labelled cells in the blood of an individual with acute myelocytic leukaemia

after tritiated thymidine reported by Cronkite[4]. In contrast, in patients with chronic myelocytic leukaemia the configuration of the leucocyte kinetic curves is much more complex. There is very early labelling with the appearance of two and often three peaks. These secondary peaks were also observed by the Brookhaven group on analysis of autoradiographs of peripheral blood from patients with chronic myelocytic leukaemia labelled with tritiated thymidine[5]. The secondary peaks were seen only at the lower grain thresholds and were considered to be fluctuations within the range of the theoretical counting error. However, since these secondary peaks are consistent and reproducible by scintillation counting, they are probably not merely random fluctuations. Recently, the Brookhaven group has suggested that the variations may be of physiological significance[6]. The interpretation of these peaks awaits analysis of autoradiographic material.

Finally, it is of interest that, kinetically, patients with acute myeloblastic leukaemia and patients in blastic crisis appear quite similar. In both instances there is early labelling with a rapid rise to peak radioactivity within a short time. It suggests that the cells in these diseases may be entering the circulation at a very rapid rate. Unfortunately, the complete curves have not been obtained in either situation as it has not been possible to continue beyond 4 or 5 days because of medical considerations.

Although tritiated thymidine is the best label for DNA which is at present available, it has a number of disadvantages. These have been considered extensively in previous publications, but the most serious problem in autoradiographs of blood smears is the low and variable geometric efficiency of tritium, which may be less than 5 per cent (ref. 7). This makes precise grain counting difficult and results in inaccurate estimates of cell kinetics. Using the scintillation counting technique, efficiency for tritium is greatly increased. In addition, it is possible to evaluate a greater number of cells than is usually read in autoradiography. Finally, background labelling, which often presents serious difficulties in interpretation of lightly labelled cells, is not a problem in scintillation counting. The principal disadvantage of scintillation counting for the study of leucocyte kinetics is the inability to discriminate among different cell types. However, by using both techniques simultaneously, it may be possible to overcome the most serious problems in the interpretation of leucocyte kinetic data. Such an investigation is now being carried out.

INDUCTION OF MULTIPLE BRAIN TUMOURS (GLIOMATA AND LEPTOMENINGEAL SARCOMATA) IN DOGS BY ROUS SARCOMA VIRUS

By Dr. G. F. RABOTTI, A. S. GROVE, jun., R. L. SELLERS and W. R. ANDERSON

Laboratory of Viral Carcinogenesis, National Cancer Institute, and Section on Neuroradiology, National Institute of Neurological Diseases and Blindness, National Institutes of Health, Bethesda, Maryland

ATTEMPTS to produce autogenic (primary) malignant tumours in large mammals have usually been unsuccessful. No experimental model has yet been developed in which a predictable host response can be obtained under specified conditions governing exposure to a carcinogenic agent. Since proof of malignancy by transplantation is not feasible in large animals, the clinical-pathological characteristics of malignancy should be carefully followed. They may be briefly summarized: (*a*) histological and cytological evidence of malignancy; (*b*) progression by invasion of the surrounding tissues resulting in the death of the host; (*c*) metastasis from those types of induced tumours which are known to metastasize when occurring spontaneously. In the specific case of viral oncogenesis, cell-free preparations of virus (of known titre) should be used in order to avoid complicating immunological factors such as graft rejection.

In the experiments reported here, young dogs were inoculated intracerebrally with high doses of cell-free preparations of Rous[1] sarcoma virus (RSV). In a relatively short time, the dogs developed multiple brain tumours fulfilling the requirements of malignancy already stated. Oncogenicity of RSV has previously been documented in mice, rats, guinea-pigs and monkeys[2–7].

RSV cell-free pools of Bryan[8] strain (*B*-RSV) and of Schmidt-Ruppin[9] strain (*S*-RSV) were prepared from White Leghorn chicken wing-web tumours by the technique of differential centrifugation[10]. These two strains of RSV were shown to be capable of inducing gliomata in new-born hamsters inoculated intracerebrally[11,12]. The virus was suspended in 0·153 M potassium citrate and preserved at −70° C in sealed ampoules. For inoculation, the virus was concentrated and resuspended in phosphate buffer saline *p*H 7·2 (PBS) as previously described[11]. The preparations were titrated against a known standard in chorioallantoic membrane from embryonated hens' eggs.

Five litters of mongrel dogs (identified in Table 1 by numerals I–V) were used in these experiments. A total of 29 dogs were inoculated in the midportion of the right cerebral hemisphere (at a depth of from 5 mm to 10 mm) using a 20-gauge needle. Different volumes of virus suspension were used depending on the size of the dog. The

titres of these inocula, expressed in focus-forming units (F.F.U.), are shown in Table 1. In addition, two new-born dogs were inoculated subcutaneously in the right flank, one with $8{\cdot}4 \times 10^7$ F.F.U. of *B*-RSV, pool No. 35, and the other with $7{\cdot}5 \times 10^7$ F.F.U. of *B*-RSV, pool No. 39. Of the 29 animals receiving the intracerebral inoculations, three died within the first 72 h after treatment and three were killed accidentally. The results in the remaining 23 dogs are summarized in Table 1.

Neurological symptoms began as early as 15 days after inoculation. The dogs often became somnolent and opisthotonic or occasionally developed ataxia and unilateral hemiparesis. One dog suddenly became paraplegic while others showed marked cachexia. Unilateral proptosis and limb weakness were frequently found.

Five animals were kept until they died, while others were killed when they became moribund. Fourteen were killed in fair to good condition when they were 25–53 days old. Autopsies were performed on all of them. At gross examination, multiple tumour nodules were frequently found on the surface of the brain. They were generally more numerous near the infundibulum and in the posterior fossa. Hydrocephalus was often present and haemorrhagic areas were occasionally noted. Microscopically, multiple tumours were found on the pia-arachnoid and within the brain (Fig. 1*A*).

Table 1. DOGS INOCULATED INTRACEREBRALLY AT DIFFERENT AGES WITH RSV, SCHMIDT-RUPPIN AND BRYAN STRAINS, OBTAINED FROM CHICKEN WING-WEB SARCOMATA. THE VIRAL INOCULUM WAS TITRATED IN CHORIO-ALLANTOIC MEMBRANE OF EMBRYONATED HENS' EGGS. VALUES ARE EXPRESSED IN FOCUS-FORMING UNITS (F.F.U.)

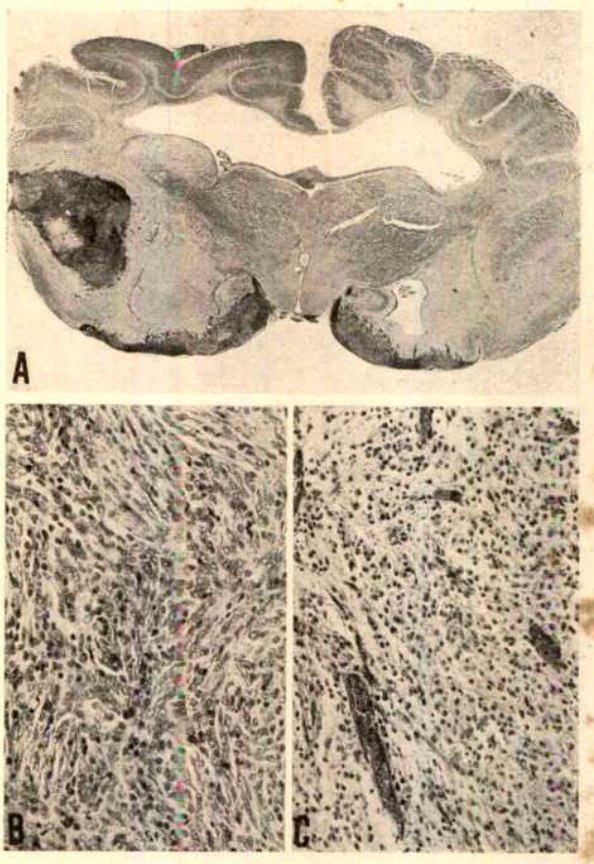

Fig. 1. Dog No. 2/I, 30 days old, injected intracerebrally at birth with $7{\cdot}4 \times 10^7$ F.F.U. of RSV, Schmidt-Ruppin strain. (*A*) Coronal section. Note multiple infiltrating sarcomata located on the cortical surface and the periventricular glioma (× *c.* 20). (*B*) Undifferentiated leptomeningeal sarcoma (× *c.* 235). (*C*) Subependymal astrocytoma (× *c.* 235)

The pia-arachnoid tumours were found to be poorly differentiated meningeal sarcomata, composed of cells which had oval vesicular nuclei and basophilic cytoplasm with thick processes (Fig. 1*B*). The deeply situated tumours were located in the periventricular subependymal tissue. These were made up of round glial cells with basophilic cytoplasm, thin fibrillar processes and numerous mitotic figures. These findings are consistent with the histological diagnosis of astrocytoma (Fig. 1*C*).

In one dog, a neoplasm found in the lungs was interpreted as a primary virus-induced tumour rather than a true metastasis. Subcutaneous fibrosarcoma-like nodules were frequently found over the site of intracerebral injection. These were probably induced by leakage of the virus along the needle tract. The failure of the virus-induced tumours to give rise to any clearly evident metastases is similar to the behaviour of spontaneous human and dog brain tumours, which rarely metastasize.

The two new-born dogs which were inoculated subcutaneously developed nodules which regressed within 30 days. The subcutaneous nodules in the scalps of the dogs which received intracerebral injections frequently grew smaller if the dogs survived for more than 1 month. Similarly regressing subcutaneous fibrosarcoma-like tumours induced by RSV have been observed in rabbits[13,14] and monkeys[15].

Three control animals inoculated intracerebrally with virus suspension thermally inactivated at 70° C for 15 and 60 min did not develop neoplasms during the 38-day

observation period. Chickens were injected intracerebrally in parallel with the dogs, using both active and heat-inactivated virus. Chickens inoculated with the heat-inactivated virus showed no evidence of tumour growth.

To the best of our knowledge, the tumours reported here are the first brain tumours which have ever been induced by viruses in large animals.

We thank Dr. H. L. Stewart, the National Cancer Institute, and Dr. K. Earle, the Armed Forces Institute of Pathology, for a critical review of the histological sections; Dr. W. R. Bryan, of the National Cancer Institute, and Drs. E. A. Bering, G. Di Chiro, W. E. Heston, R. Manaker, F. J. Rauscher, and S. E. Stewart for advice.

A DEMONSTRATION OF ION-EXCHANGE PHENOMENA IN PHOSPHOLIPID MONO-MOLECULAR FILMS

By EDUARDO ROJAS

Laboratory of Biophysics, National Institute of Neurological Diseases and Blindness, National Institutes of Health, U.S. Public Health Service, Bethesda, Maryland

AND

Dr. J. Y. LETTVIN and W. F. PICKARD

Research Laboratory of Electronics, Massachusetts Institute of Technology

SINCE Rb^+ is a substitute for K^+ and Li^+ is a substiute for Na^+ in axonal potentials[1–3], the size and chargetof an ion have been thought by some to determine its pass age through the cell membrane[4]. The ionic radius of Cs^+ is 0·21 Å greater than the ionic radius of Rb^+ and is 1·09 Å greater than the ionic radius of Li^+ (ref. 5). One might expect, therefore, that Cs^+ would substitute for K^+. Experiments indicate, however, that Cs^+ acts neither like K^+ nor like Na^+ (refs. 2, 6). It has also been proposed that La^{+++} can displace Ca^{++} on the outer surface of the cell, since La^{+++} reversibly blocks the excitability of the axon and, when it is used as a stain in electron microscopy, the gap substance between myelinated axons appears densely stained[7,8]. In contrast with the large number of demonstrations of ion effects on the axon membrane, there have been relatively few experiments on the chemistry of these phenomena. The use of monomolecular films as structural models of the cell membrane[9] provides a system the properties of which could, by analogy, give insight into this matter.

Earlier experiments[9,10] indicate that among the molecular components of the cell membrane, phosphatidylserine may provide negatively charged sites for cation exchange. In the present work, therefore, emphasis was placed on phosphatidylserine films. Silicic acid chromatography was used to isolate this phospholipid from 'animal cephalin' (Nutritional Biochemical Co.) and its purity was tested by ascending paper chromatography[9].

The uptake of Ca^{++} from a hypophase containing 0·1 mmole calcium chloride at *p*H 6·00 ± 0·25 was measured by counting the number of β particles emanating from the surface of a hypophase containing calcium-45 before and after spreading of a phospholipid monolayer. An increase in count was interpreted to indicate adsorption of Ca^{++} to the film. The technique has been described in detail elsewhere[9].

The experiments of displacing Ca^{++} from phosphatidylserine monolayers by Li^+, Rb^+ and Cs^+ were designed to show whether these monolayers would discriminate between Li^+, Rb^+ and Cs^+. The amount of calcium-45 adsorbed by the film in the presence of different concentrations of lithium chloride, rubidium chloride and caesium chloride in the hypophase was taken as a measure of the efficiency of displacement of Ca^{++} by Li^+, Rb^+ and Cs^+.

Fig. 1 shows that Li^+, Rb^+ and Cs^+ each displace the same number of calcium ions from the polar groups of the phosphatidylserine monolayer at any given concentration. This experiment substantiates previous findings[9] with Na^+ and K^+ and demonstrates that there is no discrimination among these monovalent cations. Also, it demonstrates that Ca^{++} adsorption depends on competing cation concentration.

The polar head of a phospholipid molecule would have a variable net ionic effect as determined by polar group configuration. It was thought that contaminating the monolayer with an interacting molecule such as cholesterol[11,12] would alter the polar group configuration so as to modify the position of the different ionogenic groups of the phospholipid molecule as previously postulated[13]. If this were so, the contaminated monolayer would show different ion association properties and, perhaps, selectivity. Fig. 1 shows that addition of cholesterol (Sigma Chemical Co.) does not modify the result obtained with phosphatidylserine alone. For example, the number of calcium ions per phosphatidylserine molecule is 0·23 ± 0·04 for phosphatidylserine monolayers and is 0·19 ± 0·05 for 50 per cent phosphatidylserine; 50 per cent choles-

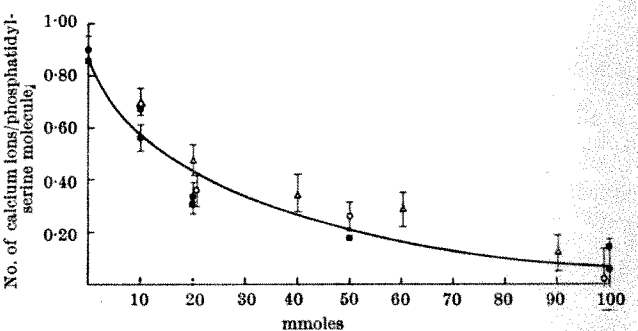

Fig. 1. Calcium displacement as a function of hypophase competing cation concentration. The vertical axis represents the number of calcium ions per phosphatidylserine molecule. The horizontal axis represents the concentration of competing counter ion in the hypophase. Each point represents the average of 3–8 experiments and the vertical bars represent twice the standard error. Area per molecule about 58 Å². Hypophase and monolayer, ●, CsCl, 0·1 mmole $CaCl_2$, PS; ○, LiCl, 0·1 mmole $CaCl_2$, PS; △, RbCl, 0·1 mmole $CaCl_2$, PS; ■, CsCl, 0·1 mmole $CaCl_2$, PS/C. PS, Phosphatidylserine; C, cholesterol

terol monolayers when the hypophase contained 50 mmole caesium chloride.

Thus, it seems to have been established that the adsorption of Ca^{++} by phosphatidylserine monolayer is equally prevented by equal concentrations of any of the following cations: Li^+, Na^+ (ref. 9), K^+ (ref. 9), Rb^+ and Cs^+. There are, however, some uncertainties about whether or not ion exchange occurs. Furthermore, no information is available about the time-course of this ion exchange.

The adsorption of Pm^{+++} (promethium) from a promethium chloride ($PmCl_3$) hypophase at *p*H 6·00 ± 0·25 was measured to determine whether or not ion exchange really occurs between the polar groups and the hypophase and to compare binding efficiency of Ca^{++} and La^{++} by measuring promethium-147 adsorption at different concentrations of calcium chloride or lanthanum chloride ($LaCl_3$).

Fig. 2 shows the time-course of the promethium-147 adsorption when the hypophase contains calcium chloride or lanthanum chloride. It can be seen that time is needed to reach the steady adsorption. Since phosphatidylserine is in its hydrogen form at the beginning of the experiment (as determined by flame photometry), the increase in counts measures the exchange of hydrogen (or Ca^{++} or La^{+++} also present in the hypophase) by Pm^{+++}. It can also be seen that about 500 times more Ca^{++} than La^{+++} is needed to produce the same equilibrium adsorption, starting from the same promethium chloride hypophase. From this experiment it can be concluded that (*a*) ion exchange actually occurs between the polar groups of the phospholipid mono-molecular film and the hypophase and (*b*) that La^{+++} is a strong competitor for the Ca^{++} binding sites. Therefore, the notion that La^{+++} displaces Ca^{++} from binding sites at cell surfaces seems to be well supported and could explain why La^{+++} reversibly blocks the excitable membrane and why the gap substance between myelinated axons appears densely stained when La^{+++} is used as stain in electron microscopy[7,8]. Finally, the idea of an ionic exchanger polar-group phase associated to phosphatidylserine mono-molecular films[9] seems to be supported and is consistent with both the molecular model for the cell membrane[14] and ion-exchange properties postulated for cell surfaces[15,16].

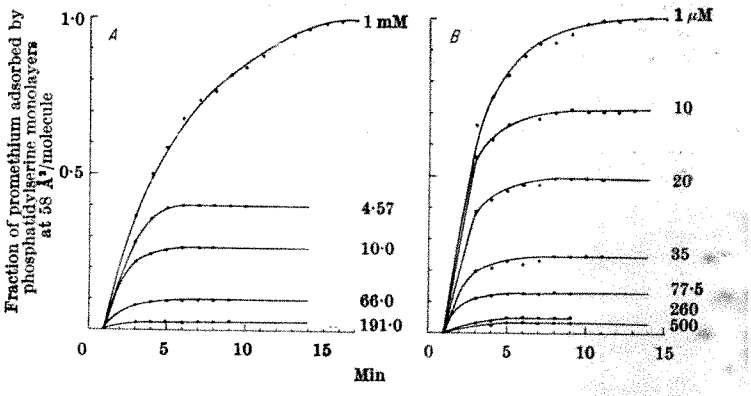

Fig. 2. Vertical axis represents the fraction of promethium adsorbed by phosphatidylserine monolayers, that is, adsorption of promethium when the hypophase contains a given concentration of calcium chloride (Fig. 2*A*) or lanthanum chloride (Fig. 2*B*) divided by the adsorption of promethium when the hypophase contained only 1 mmole lanthanum chloride. Each curve represents one experiment. Horizontal axis represents time in min starting with the solution without the monolayer. The film was spread at time 1 min and the maximum increase in count due to the film was 20,000 c.p.m. *A*, Hypophase, 1 μmole lanthanum chloride and calcium chloride; *B*, hypophase, lanthanum chloride

A RE-INTERPRETATION OF THE ROLE OF THE MAST CELL

By Dr. J. CHAYEN, SALLY DARRACOTT and W. W. KIRBY*
Department of Pathology, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2

ALTHOUGH the lung and uterus of rats are known to contain very few mast cells[1], it was found that structures resembling these cells were apparent in sections which had been stained by the histochemical reaction for monoamine oxidase[2]. These tissue elements did not appear to be coloured by the formazan developed in this reaction, but were yellow-brown, as if they had formed an adrenochrome-like pigment from the tryptamine used in the histochemical test. They could not be identified when this substance was excluded from the test, nor could they be found when un-incubated sections were examined fresh, or after staining with methyl green and pyronin. This indicated that the incubation, or the catecholamine, may have induced some change in these elements that caused them to become apparent. To test this possibility, serial sections of the lung of a rat of 5–6 weeks of age were stained with methyl green and pyronin after incubation for 2 h in the medium used in this test, with and without the tryptamine, or with histamine in its place. In all, there was a noticeable increase in the population of mast cells over that seen in sections which were not incubated before they were stained.

However, to test this hypothesis more carefully, pieces of lung from rats, 5–6 weeks old, were maintained in a synthetic, non-proliferative culture system as described by Trowell[3]; each piece weighed about 2 mg. After 24 h of such culture, some pieces were removed and chilled at −70° C in hexane (B.D.H.: "free from aromatic hydrocarbon" grade); the medium in which the other pieces were maintained was changed to a similar solution which also contained 10^{-4} M histamine. In one experiment pieces were taken 5, 15 and 30 min after this change; in the others after only 15 and 30 min; all were chilled in hexane at −70° C. Sections were cut at 8μ in a cryostat refrigerated to about −30° C in which the knife was further cooled with solid carbon dioxide packed around its haft.

* Present address: c/o Biology Division, Unilever Research Laboratories, Sharnbrook, Bedford.

They were stained with a mixture of methyl green and pyronin both to demonstrate the structure of the tissue and to aid the recognition of the mast cells. In other studies it was found that the cells which were identifiable as mast cells by this procedure seemed to correspond with those seen, albeit more weakly, with toluidine blue. The area of the sections was measured by planimetry of the image, magnified by the use of a photographic enlarger.

When fresh tissue sections were studied in this way, those of lung taken direct from the rat showed about two mast cells per cm^2 of section. In two series of experiments, culturing for 24 h alone increased the number to 8 and 4 per cm^2. However, the effect of adding histamine to the medium was more profound. The number increased to 20 per cm^2 after exposure for 5 min to this substance in culture; it became 40 and 66 after contact for 15 min and then declined to 0 and 13 after exposure for 30 min to histamine. These results are mean values for a number of sections. In contrast, this effect was not found if the tissue was kept at $-70°$ C for some days before it was sectioned and stained. This may be related to other histochemical changes found when such chilled tissue is stored at this temperature. Qualitatively, the mast cells observed after contact for 15 min with histamine were large and swollen, with prominent strongly staining granules, whereas after 30 min contact there were many granules lying in what appeared to be burst cells. The mast cells in both the treated and the normally cultured tissue occurred mainly at the periphery; this may be a reflexion of the conditions of culture.

The brown reaction given by the tissue elements suspected of being mast cells was investigated both in rat lung which had been maintained in culture, and in sections of mouse skin which had been subjected to a carcinogenic agent, tri*cyclo*quinazoline (TCQ) or to its various derivatives[4]. The advantage of the mouse tissue was that there was a profusion of mast cells localized in a definite region; they were stained distinctly by the methyl green-pyronin method. In every case, but particularly clearly at the base of the growth produced by prolonged treatment with the carcinogenic agent, the mast cells stained strongly with the histochemical method for monoamine oxidase even when 'Marsilid' was added as an inhibitor of monoamine oxidase activity in normal cells; however, the mast cells were coloured yellow-brown, or purple-brown, and not with the colour usually associated with the formazan of nitroblue tetrazolium. Similarly, in sections of carcinogen-treated mouse skin, a moderate yellow-brown colour was found in the mast cells of sections which had been incubated in the presence of histamine and nitroblue tetrazolium, which gave no reaction in the cells of the rest of the skin.

From these results two main features emerge. First, it would seem that mast cells, in the rat, can be hidden in tissue but that they swell and so become visible in response to these conditions of culture and, more strikingly, to histamine. This seems clear since, because the tissue was isolated and maintained in culture, the increase in numbers could not be due to migration into the tissue. The change in shape and size, effected by exposure to histamine, supports such a view. The second feature derives from the histochemical finding that, although these mast cells do not seem to contain appreciable amounts of amine oxidase activity, they do produce a yellow-brown pigment in response to tryptamine and, more weakly, even to histamine; the presence of a hydrogen-acceptor, here nitroblue tetrazolium, may be beneficial to this process. These results may indicate the presence of a system which can form an adrenochrome-like substance.

At first sight these findings and conclusions seem rather confusing since they appear to be at variance with the usual concept of the function of mast cells. It is generally believed[1,5] that mast cells accumulate in damaged regions and eject histamine into such tissues. This belief is largely based on the facts that mast cells are found in large numbers in damaged tissues, that they contain a bound form of histamine, and that they may become disrupted and apparently lose their granules in damaged tissue which shows the traumatic effects of histamine. In the present investigation it has been shown that exogenous histamine caused an apparent accumulation of mast cells but, since they could not have come from the synthetic culture medium, it is more likely that the histamine merely made them visible. Moreover, it was found that, although exogenous histamine allowed them to swell, prolonged exposure to such a high concentration burst the cells and disrupted the granules. It would appear that catecholamines and related substances are capable of changing the permeability of the membranes of mast cells just as they do those of other tissue cells (unpublished data). Thus it is possible to re-interpret the evidence underlying the concept that mast cells congregate in damaged tissue and contribute to the damage by ejecting histamine: it is more likely, on the data presented in this article, that they are responding to elevated levels of tissue-histamine. The other reason for considering mast cells to be emitters of histamine is that they have a high concentration of bound histamine[1,5]. However, the evidence that they may have a system which is capable of converting tryptamine and histamine into a pigment, like an adrenochrome or a melanin, indicates that they may be 'detoxicating' histamine rather than ejecting it. Only with grossly excess tissue-histamine would they become disrupted and release their normally bound histamine into the tissue. Such concepts may be of considerable significance not only in problems concerning tissue injury generally but also in anaphylactic shock[1].

LARGE AMOUNTS OF DEOXYPHENYLALANINE IN THE HYDROLYSATE OF MELANOSOMES FROM HARDING–PASSEY MOUSE MELANOMA

By Dr. H. TAKAHASHI* and Prof. T. B. FITZPATRICK
Department of Dermatology, Harvard Medical School, Boston, Massachusetts

DOPA has never been shown to be a constituent of any type of protein, although it has been found in free form in the seeds of certain plants[1–3]. This article reports our finding that it is possible to isolate and identify dopa from Harding–Passey mouse melanoma by hydrolysis of the trichloroacetic acid (TCA) precipitate of homogenized tumour tissue with strong hydrochloric acid.

Two types of melanoma were investigated: Harding–Passey melanoma (HP) grown in albino Swiss mice, and *B*-16 melanoma grown in *C*-57 black mice. Immediately after excision, 2 g of the tumour to be investigated was

* Present address: Department of Clinical Oncology, Cancer Research Hospital, Wisconsin University Hospitals, Madison 6, Wisconsin.

homogenized in 100 ml. of 10 per cent TCA, centrifuged, again thoroughly homogenized in 10 ml. of fresh 10 per cent TCA and then recentrifuged. The precipitate thus obtained was hydrolysed for 12–18 h in 300 ml. of 6 N hydrochloric acid with refluxing, cleansed of melanin by filtration through a glass funnel and evaporated almost to dryness. Half the residue was used for chromatographic isolation and spectrofluorophotometric assay[4] by a method recently devised in our laboratory. The pooled TCA supernatant was diluted with about 5 volumes of water and placed on a 'Dowex-50-H$^+$' resin column (1·0 × 6·0 cm) for removal of the TCA. The column was then washed with 50 ml. of 0·2 N hydrochloric acid followed by 100 ml. of water. The material still remaining on the resin was eluted with 100 ml. of 0·5 N hydrochloric acid, evaporated to dryness under reduced pressure at low temperature (50°–60° C), and subjected to dopa analysis[4].

The amounts of dopa recovered from 2-g specimens were: 1·0 μg/g and 230·4 μg/g of fresh tissue respectively from the HP supernatant and precipitate; 0·6 μg/g and 8·4 μg/g of fresh tissue from the *B*-16 supernatant and precipitate. In a second series of experiments with 5 g of tumour tissue, the TCA supernatants were found to contain almost negligible amounts of dopa, while hydrolysates of the TCA precipitates of HP and *B*-16 tumours contained approximately 239 μg/g and 11 μg/g of fresh tissue respectively. These findings indicate that neither type of tumour contained an appreciable amount of free dopa, but that relatively large amounts of dopa were present in the TCA precipitates of HP tumour after hydrolysis with strong acid. Dialysis of the TCA precipitates against water and repeated freezing of suspensions of the precipitates failed to release dopa into the suspending medium.

To permit accurate identification of the compound that gave high dopa-like values in chromatographic analysis of the hydrolysate of the TCA precipitate of HP melanoma, three experiments were carried out with large amounts of HP melanoma tissue. In each of these experiments, 100 g of freshly excised HP melanoma were thoroughly homogenized in 200 ml. of 20 per cent TCA and centrifuged until the precipitate separated out. The resulting supernatant was discarded; the precipitate was again homogenized in 100 ml. of 20 per cent TCA and centrifuged a second time. The dark precipitate obtained from this second centrifugation was hydrolysed for 24 h in 1,000 ml. of 6 N hydrochloric acid with refluxing, 100 ml. of concentrated hydrochloric acid being added twice during the 24-h period. After hydrolysation, the insoluble melanin was removed by centrifugation. The supernatant was concentrated to a syrup under reduced pressure at low temperature (50°–60° C) and redissolved in 1,000 ml. of water. An extra step was necessary to remove the excess acid and other extraneous material from this syrup. The syrup was therefore redissolved in 1,000 ml. of water and put on a 'Dowex-50-H$^+$' resin column. After it had passed through the column the resin was washed with 1,000 ml. of 0·2 N hydrochloric acid followed by 2,000 ml. of water. The material still remaining on the resin was then eluted with 2,000 ml. of 0·5 N hydrochloric acid. The eluate was evaporated to dryness under reduced pressure at low temperature. Since dopa is relatively stable in basic borate buffer[4,5], 1,000 ml. of borate buffer (*p*H 9·0) containing 7·63 g of sodium borate and 0·62 g of boric acid were added to the evaporated eluate and the *p*H adjusted to approximately 8·6 with dilute sodium hydroxide solution. For convenience of manipulation, the resulting preparation was divided into ten 100-ml. aliquots, each of which was diluted with 100 ml. of water. These aliquots were applied to ten 'Dowex-2-borate$^-$' resin columns and ten 'Dowex-50-H$^+$' resin columns[4]. The eluates thus obtained were then pooled and evaporated to dryness under reduced pressure at low temperature. The dried residue was dissolved in 25 ml. of aqueous borate buffer (*p*H 9·0) and further purified by gradient-elution chromatography on a 'Dowex-2-Cl$^-$' resin column (2·0 × 15·0), 800 ml. of 0·5 per cent aqueous boric acid solution being used as the mixer and 0·5 per cent boric acid in 0·3 N hydrochloric acid as the reservoir. 6-ml. fractions were collected at a flow rate of 1 ml./min. Before elution started, 20 ml. of 0·5 per cent aqueous boric acid solution was layered over the top of the column to prevent mechanical disturbance. The ultra-violet absorption spectra of the compounds recovered from the column were determined by spectrophotometry.

An unidentified compound (*A*), the ultra-violet absorption of which was maximal at 281 mμ, appeared first in fraction No. 27 and was last present in fraction No. 37; its concentration was highest in fraction No. 28. A very small amount of material (*B*), the ultra-violet absorption of which was maximal at 275 mμ, was found in fraction No. 17—the fraction that theoretically should contain tyrosine. The total quantities of compound *A* recovered in the three experiments were 16, 12 and 11 mg when calculated as dopa from the optical density at 281 mμ of the dopa standard.

The fractions containing compound *A* from all three experiments were pooled and again put on a 'Dowex-50-H$^+$' resin column (2·0 × 5·0 cm) for further purification by gradient-elution chromatography. 400 ml. of water was used as the mixer, 8 N hydrochloric acid was the reservoir, the fractions were each 6 ml., and the flow rate was 1 ml./min. Compound *A* was found to be present in fractions No. 23 to No. 33. These fractions were pooled and evaporated to dryness under reduced pressure at low temperature. After hydrochloric acid had been removed in a sodium hydroxide–calcium chloride desiccator, the compound was dissolved in 4 ml. of distilled water and brought to approximately *p*H 5 by the careful addition of sodium bisulphate. About 1 ml. of ethanol was added before this purified material was crystallized in a deep freeze. Finally, the crystals were centrifuged and washed with 1·0 c.c. of cold distilled water and dried in a desiccator. The amount obtained was approximately 34 mg.

Absorption of ultra-violet light by purified compound *A* was maximal at 281 mμ in 0·5 N hydrochloric acid; absorption of ultra-violet by the known dopa standard was also maximal at 281 mμ in the same medium.

When compound *A* was oxidized by ferri-cyanide (0·05 per cent in 1 M acetate buffer) at *p*H 6·0 and made alkaline with 20 per cent aqueous sodium hydroxide containing ascorbic acid[4], the spectra of the activation and emission of fluorescence were identical with those of a standard dopa control preparation, the maxima for activation and emission being 375 and 480 mμ respectively (Figs. 1 and 2).

When compound *A* and its product were tested by paper chromatography following incubation with tyrosine

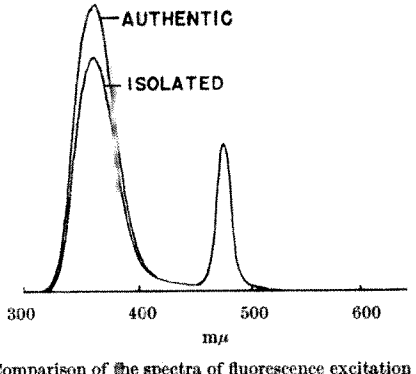

Fig. 1. Comparison of the spectra of fluorescence excitation (emission at 480 mμ) for the compound isolated from Harding–Passey melanoma and the control sample of dopa after oxidation with ferri-cyanide[4]. The curve of excitation for the material isolated from HP melanoma is lower than that for the control solution due to the presence of inorganic impurities. Fluorescence was measured with an Aminco–Kiers spectrofluorophotometer at slit No. 3. The concentration of both samples was 1 μg/ml.

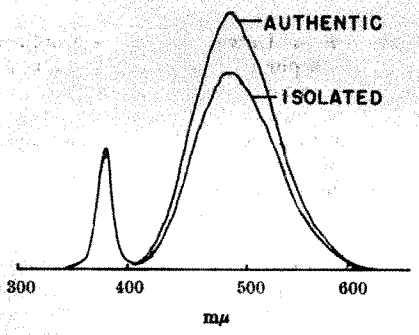

Fig. 2. Comparison of the spectra of fluorescence excitation (excitation at 375 mμ) for the compound isolated from Harding–Passey melanoma and the control sample of dopa after oxidation with ferri-cyanide[4]. The curve of excitation for the material isolated from HP melanoma is lower than that for the control solution because of the presence of inorganic impurities. Fluorescence was measured with an Aminco–Kiers spectrofluorophotometer at slit No. 3. The concentration of both samples was 1 μg/ml.

decarboxylase in the presence of pyridoxal phosphate, spots were produced identical with those produced by dopa and dopamine; compound *A* and the controls had identical R_F values in three different solvent systems under sulphur dioxide and produced the same colour changes in the ferri-cyanide reagent, — red → purple → black (Fig. 3).

When compound *A* was incubated with mushroom tyrosinase in phosphate buffer at *p*H 6·8, the red colour that instantly developed had a broad ultra-violet absorption band with a flat peak at about 475 mμ; this could not be distinguished from that of the red colour of the dopachrome produced in the dopa : mushroom-tyrosinase reaction.

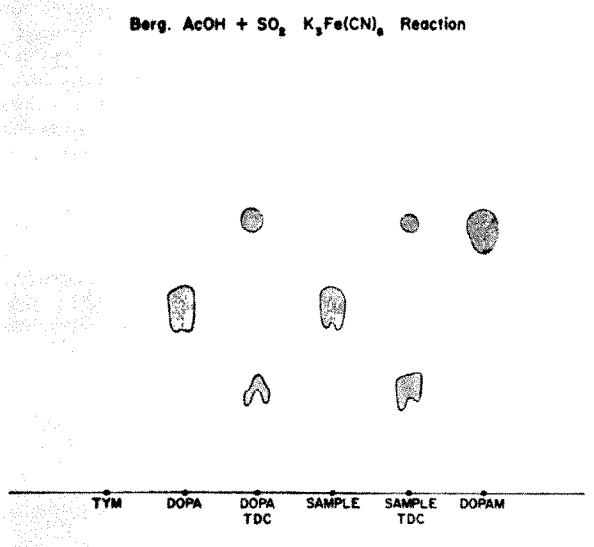

Fig. 3. A paper chromatogram of the compound isolated from HP melanoma and its product after incubation with tyrosine decarboxylase. The solvent system consisted of Berg's solvent (methanol : butanol : benzene : water in the proportion of 2 : 1 : 1 : 1) acidified with 1 per cent glacial acetic acid. The chamber of the chromatograph was filled with gaseous sulphur dioxide. For identification of the *o*-dihydroxyphenolic compounds, the paper was sprayed with 0·05 per cent potassium ferri-cyanide in 0·2 M acetate buffer (*p*H 6·0)

To determine the intracellular localization of compound *A*, which is probably contained in a protein, 10 g of HP melanoma were homogenized in about 9 volumes of 0·3 M aqueous sucrose solution and separated into cell-organelle fractions by the density-gradient centrifugation method[6]. After precipitation by TCA and when dried under an infrared lamp, the proteins in each fraction were hydrolysed for 12–18 h in 300 ml. of 6 N hydrochloric acid with refluxing. The insoluble melanin in each fraction was removed by filtration and the hydrolysates of the different fractions were evaporated to dryness *in vacuo* at low temperature. One-tenth of the dry residue of each fraction was used for dopa analysis.

The amounts of dopa found in the various cell fractions of HP tumours are shown in Table 2. These results indicate that most of the dopa-containing protein is localized in melanosomes where the greatest amount of tyrosinase activity is also found. The fact that various types of treatment other than hydrolysis with strong acid failed to release dopa from the melanosomes may indicate that dopa is present within the protein molecule. To verify this concept, 10 g of HP mouse melanoma were homogenized twice in 50 ml. of 20 per cent TCA; the precipitate was dialysed against distilled water to remove the TCA and then incubated for 12–18 h at 37° C with about 2 g of pepsin in 100 ml. of 0·05 N hydrochloric acid. At the end of the incubation period, the mixture was put into a 'Cellophane' bag and dialysed for 7 h against 1,000 ml. of water acidified with a few drops of hydrochloric acid. Absorption of ultra-violet light by the dialysate was maximal at 275 mμ; its optical density gradually increased during this dialysis. Half the dialysate was frozen, the other half hydrolysed in 6 N hydrochloric acid overnight with refluxing. 100-ml. aliquots of the dialysate were analysed for dopa. The total dopa content of the dialysate was 39·7 μg before hydrolysis, 97·3 μg after hydrolysis. In a similar test made with the large-granule fraction obtained from HP melanoma by density-gradient centrifugation the dialysate contained 29·7 μg of dopa before hydrolysis and 77·9 μg after hydrolysis. In both experiments the dopa content was approximately 2·5 times greater after than before hydrolysis with strong acid.

Table 1. Amounts of Dopa found in the Various Fractions of HP and *B*-16 Mouse Melanoma

	Fractions	HP (μg/g)	*B*-16 (μg/g)
1	Supernatant	1·0	0·6
	TCA ppt.	230·4	8·4
2	Supernatant	—	—
	TCA ppt.	239·0	11·0

Table 2. Amounts of Dopa found in the Various Fractions of HP Mouse Melanoma*

Fractions	Dry weight (mg)	Melanin	Dopa (μg)
Nuclear fraction	332	+ +	204
Soluble protein	571	–	32
Small granules	256	±	57
Mitochondria	306	±	30
Melanosome	940	+ + +	885

* Some fractions contained unhydrolysable melanin.

Some of the dopa released from HP-melanoma protein by pepsin digestion could have been localized at the N-terminal of the protein molecule. It is clear, however, that in addition to liberated dopa, the hydrolysate contains dopa derivatives, probably dopa-peptides. An attempt is now being made to isolate dopa peptides from weakly hydrolysed HP-melanoma protein. The absence of dopa-containing proteins in *B*-16 melanoma might indicate that there is a genetic difference in the melanosomal proteins of HP and *B*-16 melanoma which could account for the characteristic difference in the colour of these tumours.

LUTEINIZING HORMONE RELEASE FOLLOWING PREOPTIC STIMULATION IN THE MALE RAT

By Dr. DAVID L. QUINN
Department of Anatomy, Duke University Medical Center, Durham, North Carolina

DIFFERENTIATION of the neural control of gonadotropin secretion depends on sex steroid secretion shortly after birth in the male or female rat. Regardless of the genetic sex of the rat, the non-cyclic male pattern of gonadotropin secretion develops in the presence of androgen or excessive oestrogen early in life. On the other hand, in the absence of sufficient levels of sex steroids the cyclic female pattern ensues[1–3].

Experiments carried out by Harris and Jacobsohn[4] and Martinez and Bittner[5] revealed that the nervous system is the site of differentiation for the appropriate control of gonadotropin secretion, not the hypophysis as supposed by Pfeiffer[1]. Regardless of the sex of the donor, pituitary grafts beneath the median eminence of hypophysectomized male or female animals assumed the functional characteristics associated with the respective sex of the host. Pituitary tissue from either male or female rats grafted beneath the median eminence of hypophysectomized female rats maintained normal oestrous cycles[4]. Identical results were obtained in investigations in mice[5]. Furthermore, in castrated male mice bearing ovarian and vaginal grafts, continuous secretion of gonadotropins occurred when either male or female pituitary tissue was grafted beneath the median eminence.

The cyclicity of gonadotropin secretion appears to depend on sex steroids in circulation as well as on the appropriate differentiation of the neural regulatory systems. Vaginal transplants were used as indicators of rhythmic or continuous gonadotropin secretion in castrated female and male rats bearing ovarian transplants[6]. Concentric layers of cornified tissue interposed with nucleated epithelial cells and leucocytes in vaginal grafts revealed cycling of ovarian hormone secretion and therefore cyclic gonadotropin release. Cyclic gonadotropin secretion was noted only in otherwise intact females with intrasplenic vaginal grafts. When sex steroid release to the peripheral circulation was greatly reduced by grafting ovarian tissue into the spleen of the castrated male or female rat bearing intrasplenic vaginal transplants, evidence of cyclic gonadotropin secretion was absent. Cyclic gonadotropin secretion was also lacking in castrated male rats bearing intrasplenic vaginal transplants with ovarian tissue grafted outside the spleen.

'Electrochemical' stimulation of the preoptic brain in the pentobarbital-blocked rat during proestrus or on the third day of dioestrus in the 5-day cyclic rat induces the normal ovulatory response[7]. In androgen-sterilized female rats the threshold of preoptic stimulation for ovulating hormone release appears to be raised[3,8]. With these experiments in mind, an investigation was initiated in castrated adult male rats bearing ovarian grafts. Ovarian tissue under these conditions remains primarily follicular in nature[9]. It was of interest to determine whether ovulation and/or luteinization could be produced in such experimental animals by stimulation of the hypothalamus. If this were so, it would reflect the release of luteinizing hormone from the anterior pituitary.

Rats were obtained from a locally inbred Osborne-Mendel derivative strain and maintained on Purina 'Laboratory Chow' and water *ad libitum*. From birth they had been exposed to regular daily illumination for 14 h. Male rats were castrated when about 30 days old, and in each animal ovarian tissue (half an ovary) from a littermate was transplanted beneath the kidney capsule. At about 90 days of age further procedures were instituted: (1) 'electrochemical' stimulation of the medial preoptic area under pentobarbital sodium (31·5 mg/kg); (2) simple electrode placement in the medial preoptic area; (3) injection of a known ovulating dose of NIH-LH-B_1 (unpublished observations, 8 μg/100 g body-weight). The electrical parameters of stimulation were 10 μamp d.c. for a period of 20, 40, or 60 sec, and anodic current was applied through the 0·13 mm core of a stainless steel concentric bipolar electrode stereotaxically introduced. Histological procedures for ovarian and brain tissues were described previously[7].

The response of the castrated male animal to preoptic stimulation was much like that which can be expected in the female. Luteinization of the ovarian transplants followed in nearly all rats receiving stimulation by 10 μamp over a period of 60 sec (Table 1). Three animals were autopsied the morning following stimulation and showed numerous fresh corpora lutea. Some of the corpora lutea had entrapped ova, while others did not. The rest of the animals (six) in this group were autopsied 3 days after preoptic stimulation (Fig. 1). Five of six animals had ovaries with marked formation of corpora lutea (Fig. 2).

The threshold for responsiveness in the castrated male rat appears to be slightly higher than in the adult proestrous female rat. A group of animals received low intensity preoptic stimulation (10 μamp d.c./20 sec), comparable to that required to evoke ovulation in all pentobarbital-blocked proestrous rats[7]. This threshold is somewhat lower than that necessary to induce ovulation by preoptic stimulation in late dioestrus of the 5-day cyclic rat (10 μamp d.c./40 sec), and has been correlated with the lower level of luteinizing hormone required to induce ovulation in the former animals[7,10]. In castrated male rats bearing ovarian transplants, preoptic stimulation with 10 μamp/20 sec evoked the release of luteinizing hormone in four out of eight animals. Increasing the duration of the stimulus to 40 sec evoked gonadotropin release and corpus luteum formation in all animals.

Animals submitted only to the stereotaxic and operational procedures with the insertion of the electrode into the preoptic hypothalamus but without passage of electric current demonstrated uniform absence of luteinization (Fig. 3).

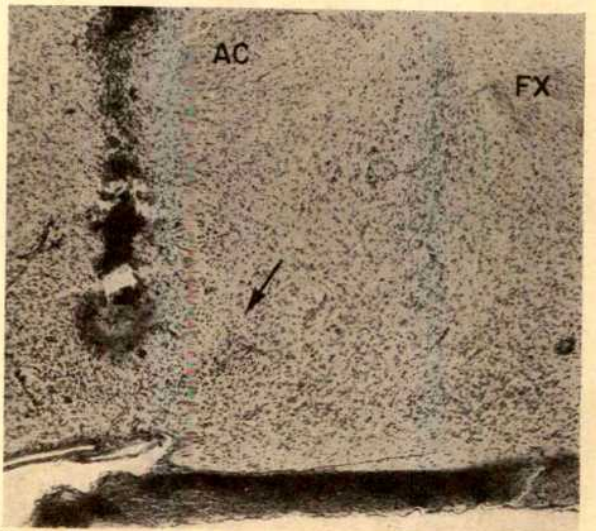

Fig. 1. Parasagittal section of brain illustrating a typical location of the electrode path and nature of the irritative focus established following 'electrolytic' stimulation (10 μamp d.c./60 sec). Arrow indicates approximate outer limit of lesion. *AC*, Anterior commissure; *FX*, fornix. (× c. 35)

Injection of a known ovulating dose of luteinizing hormone into castrated male rats with ovarian transplants produced marked luteinization.

Preoptic stimulation thus abruptly augments the release of luteinizing hormone in the male as it does in the female rat. Ovulation and corpus luteum formation occur in ovarian transplants following stimulation in the castrated male. Apparently the production and release of luteinizing hormone releasing factor by the neural tissue and of luteinizing hormone (LH) by the anterior pituitary are entirely adequate in castrated male animals bearing ovarian transplants to allow for an 'ovulatory surge' of LH following preoptic stimulation. The threshold for this response is comparable with that on the third day of dioestrus in the 5-day cyclic rat and slightly higher than that for the day of proestrus in the 4-day cyclic rat[7]. By contrast, the preoptic threshold for stimulation of LH release in the androgen-sterilized female rat is higher than in the normal female[3,8].

* 'Electrochemical stimulation' in the medial preoptic area.

Evidence from other experiments suggests the similarity in the response of the male and female rat with respect to gonadotropin secretion. Progesterone treatment in the castrated male rat bearing ovarian transplants provokes augmented release of luteinizing hormone to such an extent that corpus luteum formation takes place[11]. In the intact female, ovulation can be advanced one day (5-day cyclic rats) by progesterone treatment on the third day of dioestrus[12]. In some types of constant oestrous animals (spontaneous, light-induced, or with anterior hypothalamic lesions) progesterone treatment produces ovulation[13–16]. The failure to obtain ovulation with progesterone treatment in androgen-treated females is difficult to explain, except on the basis that the changes which take place after the treatment may be far more extreme than occur in the normal animal[16]. This situation may be comparable with that in animals with lesions in the suprachiasmatic-medial preoptic area much larger than necessary to induce constant oestrus. These animals also fail to ovulate following progesterone treatment[16].

The analogous responses of the male and female rat to preoptic stimulation or progesterone treatment suggest that the differences known to exist in the neural control of gonadotropin secretion in the two sexes may, indeed, lie outside the preoptic-anterior hypothalamic-median eminence-pituitary system. The difference may exist in the nature of the afferent impulses to this neural region or the inability of the cells in the hypothalamus to interpret the afferent impulses. The fact that the hypothalamic system in the castrated male rat bearing ovarian transplants responds in a way similar to that of the intact female cannot be over-emphasized. Apparently, the necessary quantities of luteinizing hormone-releasing factor and pituitary LH are quite sufficient to induce ovulation when the appropriate stimulus is supplied either to the male or female. Furthermore, the neural components in the hypothalamus required to bring this about are functional in the male rat.

This investigation was supported in part by U.S. Public Health Service fellowship 1 *F2AM*-23, 550-01 from the National Institute of Arthritis and Metabolic Diseases and in part by grant *GB*-1737 from the National Science Foundation administered by Dr. J. W. Everett. NIH-LH-B_1 was kindly supplied by the Endocrinology Study Section, National Institutes of Health.

Note added in proof. While this paper was in the press an abstract by Moll and Zeilmaker[17] appeared, describing experiments comparable with those presented here, but differing in that far greater stimulation was used.

POLYSOMES ON A NUCLEAR MEMBRANE FRACTION AS INTERMEDIATES IN THE TRANSFER OF RIBONUCLEIC ACID FROM THE NUCLEUS TO THE CYTOPLASM

By Dr. MICHAEL K. BACH and H. G. JOHNSON
Department of Biochemistry, The Upjohn Company, Kalamazoo, Michigan

THERE is considerable evidence to the effect that messenger RNA (*m*RNA), together with all other forms of RNA, is produced in the nuclei of mammalian cells[1]. This RNA is believed to travel to the cytoplasm, where it becomes the backbone of polysomes which are the subcellular aggregates responsible for protein synthesis[2–4]. However, little is known concerning the manner in which this RNA is conveyed to the cytoplasm, and only small amounts of free *m*RNA can be detected in the cytoplasm[5]. The possibility therefore remains that polysomal aggregates are actually formed in the nucleus or on the surface of the nucleus and travel from it as a unit. This article presents evidence for an association of polysomes with the nucleus and for the role of these polysomes as intermediates in the transfer of newly synthesized *m*RNA from the nucleus to the cytoplasm. This evidence is obtained by relying on the ability of DNA solutions to extract a specific microsome fraction from washed nuclei[6].

HeLa cells were exposed to uridine-^{3}H (U-^{3}H) (4 μc./ml.), while suspended in Eagle's minimal essential medium. Washed cells were allowed to swell in distilled water[7], homogenized with a tight-fitting Dounce homogenizer, and the medium immediately adjusted to the following composition: 0·25 M sucrose, 5×10^{-3} M magnesium chloride, 0·1 M potassium chloride, 0·05 M *tris* hydrochloric acid buffer, *p*H 7·8 (solution *A*), and 0·25 per cent Triton '*X*-100'[8]. Nuclei were removed by centrifugation at 600*g* for 15 min, and the supernatant suspension adjusted to 0·5 per cent with respect to sodium deoxycholate (*p*H 7·8) and used as the cytoplasmic fraction. The nuclei were washed several times in solution *A* plus Triton '*X*-100' and finally centrifuged through a layer of 2·2 M sucrose in solution *A* at 37,000 r.p.m. for 4 h using the '*SW*-39' rotor of the Spinco model *L* ultracentrifuge[9]. The washed nuclei, which were free from any visible cytoplasmic contamination and virtually free from intact cells, were resuspended in solution *A* plus 5 mg/ml. salmon sperm DNA and allowed to stand at 0° C for 30 min. This suspension was then diluted with two volumes of solution *A* and recentrifuged at 12,000*g* for 30 min. The supernatant was adjusted to 0·5 per cent with respect to sodium deoxycholate and will be referred to as the DNA extract of the nuclei. The remaining pellet represented the nuclear residue. When such an experiment was carried out with a short labelling period (5 min) 52 per cent of radioactivity fixed was found in the nuclear fraction and the remainder in the cytoplasmic extracts and nuclear washes. Under such conditions, about 40 per cent of the nuclear radioactivity was extracted by exposure to exogenous DNA, and this material had the physical characteristics of polysomes.

In Fig. 1, the distribution of radioactivity in sucrose gradient centrifugal separations of the cytoplasmic fraction (1*A*) is compared with that of the DNA extract of nuclei (1*B*). In such homogenates the radioactive peak present in the nuclear extract had an S^w_{20} of approximately 110–170 as compared to a nominal 70 *S* for the single ribosome peak. Comparatively little radioactivity was found in the cytoplasmic fraction after such a short labelling period (Fig. 1*A*) compared with the amount found in the DNA extract of the nuclei of the same cells (Fig. 1*B*).

Aggregates in the DNA extract were not destroyed by treatment with DNase (1*C*) while they were extremely labile to minute amounts of RNase (1*D*). This is consistent with the interpretation that these fractions were aggregates having radioactive RNA as a backbone.

The DNA which was used in the extraction did not appear to be bound in this complex in a way which would affect the aggregate size (Fig. 1*C*). This is in agreement with the results of Okamoto and Takanami *et al.*[10,11], who demonstrated that only single-stranded DNA formed complexes with ribosomes. The ability of DNA to effect this extraction was not dependent on the source of the DNA, nor on its molecular weight. Thus salmon sperm DNA was as effective as calf thymus DNA, and a shear-degraded DNA which was no longer precipitable with two volumes of alcohol was still active in extracting the polysomes from the nuclei. On the other hand, some structural specificity is required, since other polyanions such as yeast RNA, heparin, and poly-ethenesulphonic acid were inactive when tested in the same system. It

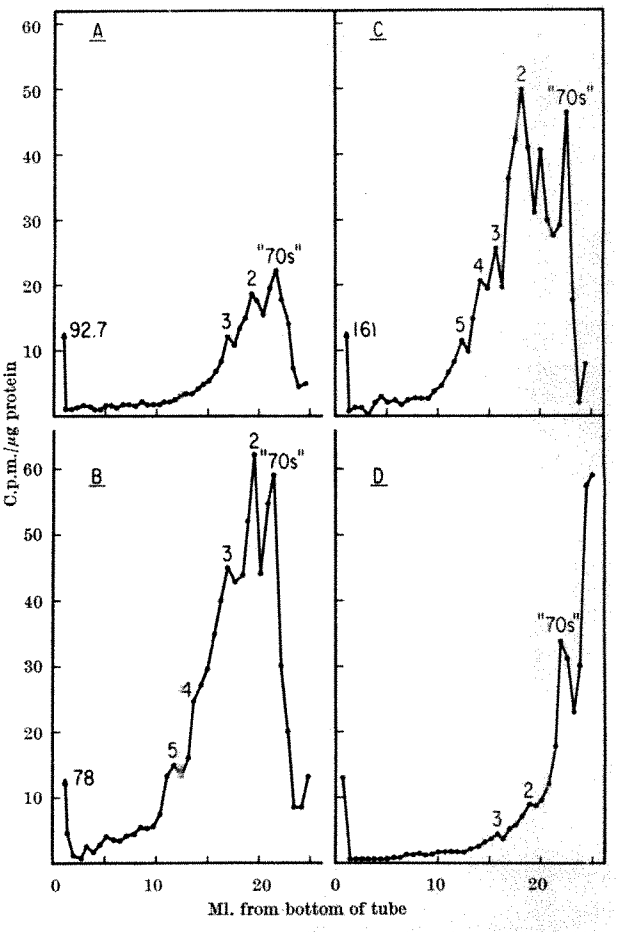

Fig. 1. Sucrose gradient centrifugation of extracts from cells labelled with U-^{3}H for 5 min. Cell fractionation as described in text. Sucrose gradients were linear (15–30 per cent) in solution *A* and contained 15 μg/ml. poly-ethenesulphonic acid mol. wt. 12,900[12]. Centrifugation was at 25,000 r.p.m. for 2 h in the '*SW* 25' rotor of the Spinco model *L* ultracentrifuge. Results represent radioactivity in the acid insoluble fraction expressed as c.p.m./μg protein. *A*, Cytoplasmic fraction; *B*, DNA extract of nuclei; *C*, DNA extract of nuclei after treatment with 2·5 μg/ml. DNase at 37° C for 5 min; *D*, DNA extract of nuclei after treatment with 0·06 mμg/ml. RNase at 37° C for 5 min

must be concluded that the DNA acted as a specific chemical extractant in this procedure.

Further evidence for the polysomal nature of the RNA aggregates found in the nuclear extract came from the examination of this fraction in the electron microscope. Large numbers of 'chains' of particles which corresponded in size to ribosomes were readily demonstrated. Finally, the molecular size of the radioactive RNA species present in the various fractions from labelled cells was estimated by means of the sodium dodecyl sulphate procedure of Gilbert[12]. As can be seen in Fig. 2, the bulk of the radioactivity fixed into each of the three fractions during a 5-min labelling period showed a very heterogeneous distribution of sizes with a peak about 10*S*, corresponding to the characteristic size distribution for *m*RNA. It is interesting that, although most of the radioactivity in the cytoplasmic fraction had been found in the 70*S* region (Fig. 1*A*), the isolated radioactive RNA from this material also corresponded to *m*RNA in size and was indistinguishable from the RNA in the DNA extract of the nuclei. On prolonged exposure to U-^{3}H, the labelling pattern in the nuclei shifted towards larger RNA species which could be ribosomal RNA precursors[13]. The change in the distribution of radioactivity in the other two fractions indicates the incorporation of label into ribosomal RNA. The total amounts of radioactivity in the various fractions also changed markedly (Fig. 2 *D–F*). The large amount of DNA (extractant) present in gradient 2*B* and 2*E* prevented the detection of the characteristic peaks of ribosomal RNA by their absorption at 260 mμ. However, colorimetric

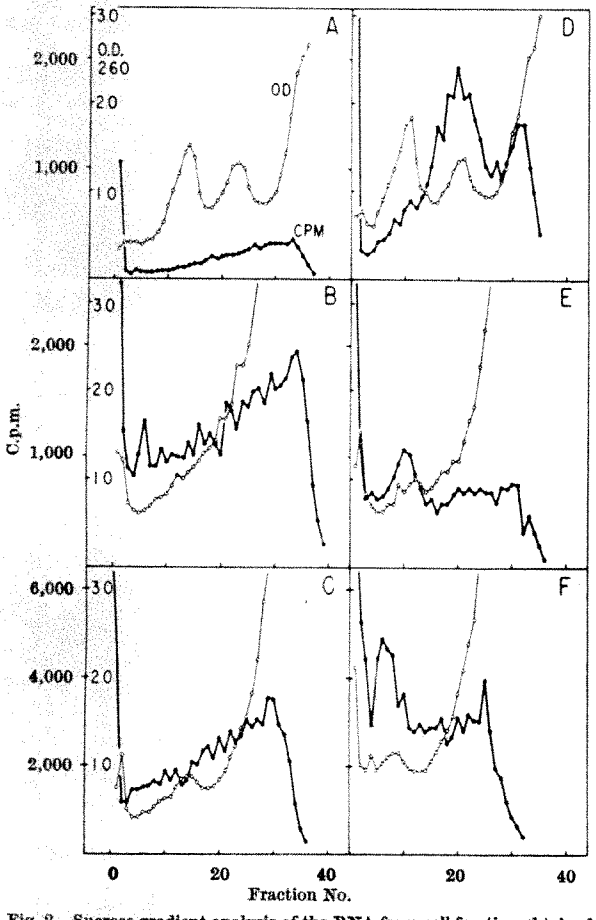

Fig. 2. Sucrose gradient analysis of the RNA from cell fraction obtained as described in text. The isolated fractions were adjusted to 0·5 per cent sodium dodecyl sulphate and layered over linear sucrose gradients (15–30 per cent) which contained 0·5 per cent sodium dodecyl sulphate[9]. Centrifugation was at 20° C, 25,000 r.p.m. for 11 h in the '*SW* 25' rotor. Closed circles, total acid insoluble radioactivity; open circles, absorption at 260 mμ. *A*, Cytoplasmic fraction, 5 min labelling; *B*, DNA extract of nuclei, 5 min labelling; *C*, nuclear residue from same fractionation; *D*, *E* and *F*, same as *A*, *B* and *C*, respectively, but after 90 min labelling

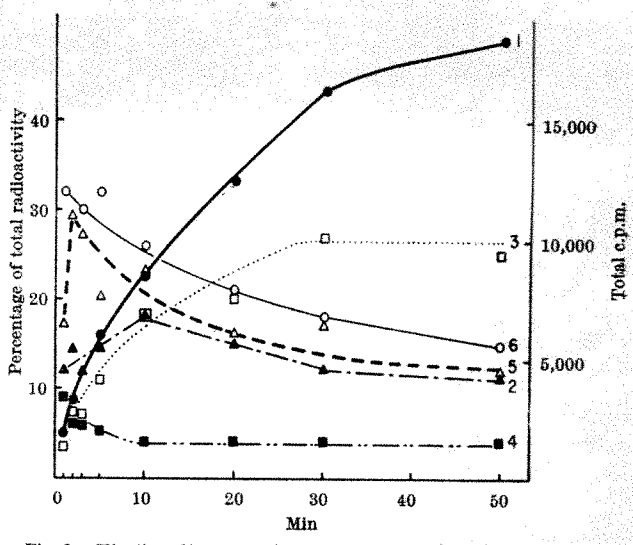

Fig. 3. Kinetics of incorporation of cytidine-^{3}H into various subcellular fractions of HeLa cells. Label was supplied as described for U-^{3}H in the text, and fractionation was as described without addition of sodium deoxycholate. Curve 1 represents uptake of radioactivity into the total fractions. Curves 2–6 represent the percentages of the total radioactivity which were found in: curve 2, cytoplasmic fraction sedimenting at 12,000*g* for 30 min; curve 3, cytoplasmic material sedimenting between 12,000*g* and 105,000*g*; curve 4, cytoplasmic soluble fraction; curve 5, DNA extract from nuclei; curve 6, residual nuclear fraction after extraction with DNA solution

determinations indicated that the RNA/protein ratio in the deoxycholate-treated fractions was approximately 0·8, typical of mammalian ribosomes.

It is questionable whether the polysomes which were associated with the nuclei represented a random sample of the cellular polysome population, as might be expected if they arose by some adsorption artefact, or whether, instead, they represented a special stage in the life-cycle of the polysomes. In order to answer this question the time course of the incorporation of tritiated cytidine into the RNA of the various cellular fractions was followed. The results of one such experiment are shown in Fig. 3. Virtually identical results were obtained on two separate repetitions of this experiment. The most rapidly labelled fraction was the RNA in the nuclear residue fraction (curve 6). The RNA present in the cytoplasmic ribosomes (curve 3) was the last fraction to become radioactive. Kinetically the polysomes of the nuclear extract (curve 5) and those associated with the cytoplasmic membranes (curve 2) behaved as intermediates in the flow of RNA from the nucleus to the cytoplasm. The results are in accordance with the view that *m*RNA is first formed in the nucleus, becomes associated into polysomes in or on the nucleus, after which the polysomes leave the nucleus in association with the membranes of the endoplasmic reticulum and finally end up as free polysomes.

The polysomes which were present after rapid pulse labelling appeared to be primarily membrane-bound. Essentially all the radioactive RNA of these cells was sedimented after centrifugation at 30,000*g* unless the preparations were first treated with sodium deoxycholate. Furthermore, both the DNA extract of the nuclei and the cytoplasmic microsome fractions had similar and typical phospholipid/protein ratios and comparable NADH-cytochrome *c* reductase activities, in agreement with the conclusion that the ribosome aggregates in these fractions were bound to membranes. This is contrary to the results of Penman *et al.*[7], who reported that the use of deoxycholate was not necessary in demonstrating the presence of polysomes in extracts of the *S*-3 clone of HeLa.

Microscopic examination of the nuclei before and after extraction with DNA failed to show any detectable change in their appearance. Furthermore, nuclear counts indicated that essentially all the nuclei were recovered following this extraction. It is thus unlikely that the membranes in

the DNA extract originated inside the nuclei. Because of the pronounced difference in the relative amount of radioactivity which was bound to the membranes in this fraction, it is likely that these membranes originated as portions of the nuclear membrane rather than from the endoplasmic reticulum.

That polysomes which are bound to membranes are more active in protein synthesis than those which are free in the cytoplasm is suggested by the findings of Haselkorn and Fried, Pelmont *et al.* and others[4,14–17]. Thus free polysomes may represent the last stage in polysome development, and the movement of the polysomes from the nucleus to the cytoplasm may take place on the membranes of the nucleus and endoplasmic reticulum. It is possible that this movement is accomplished by movement of the membranes themselves.

We thank Mr. F. LaPlante for technical assistance. Triton '*X*-100' was obtained as a sample from Rohm and Haas Company, Philadelphia, Pennsylvania.

REGULATION OF CELLULAR AUTOLYSIS BY HYPERBARIC OXYGEN

By Dr. R. M. ROSENBAUM, Dr. M. WITTNER and S. WERTHEIMER
Department of Pathology, Albert Einstein College of Medicine, New York

INHIBITION of tissue autolysis by hyperbaric oxygen was first described by Paul Bert[1], who ascribed it to an inhibition of "ferments". Few, if any, experimental data have appeared substantiating these observations or attempting to ascertain possible mechanisms of action of the inhibition. Much of this neglect may be due to the unavailability of adequate experimental material. Several desirable features, including relatively uniform and predictable survival times and ease of mechanical handling, make protozoa excellent experimental subjects for investigations of oxygen toxicity, as described by Wittner[2]. Also, ciliate protozoa such as *Paramecium* have well-developed enzymatic mechanisms for intracellular digestion of exogenous as well as endogenous food materials[3]. These attributes combined suggested that at least some of the hydrolytic enzyme systems of these protozoans could serve as test objects for an investigation of the effects of hyperatmospheric oxygen concentrations on intracellular autolytic mechanisms. For our initial observations, we chose a sulphydryl dependent, intracellular enzyme system for which *Paramecium* possesses high levels of activity.

A single line clone of *Paramecium caudatum* was established according to the method of Sonneborn[4]. For experiments, sub-cultures of feeding animals were pooled and washed several times by centrifugation at low speeds (500 r.p.m.) in successive changes of de-mineralized-distilled water.

For exposure to oxygen, aliquots of washed organisms containing 2,000–4,000 animals were placed in small open Petri dishes. The final volume of liquid was kept constant to permit equivalent diffusion paths with respect to depth and cross-section of the Petri dish. The pressure vessel was a 'Lucite' cylinder re-inforced with brass ends, as described previously[2]. Pure oxygen (Linde) was used up to pressures of 7 atm. (abs.) following thorough flushing (5 min) of the tank. Control gas mixtures consisted of a single atmosphere of air (not flushing the tank) with nitrogen to the desired number of atmospheres (abs.). Decompression occurred over a 10-min period to avoid mechanical damage to the organisms.

Our initial observations were made at room temperature (26° C) and consisted of exposing three groups of animals to 3 atm. (abs.) and 7 atm. (abs.) of pure oxygen respectively and a single atmosphere of air with the addition of 6 atm. (gauge pressure) nitrogen. Consistent with the data of Wittner[2], *Paramecia* exposed to 3 atm. of pure oxygen were killed by about 9 h exposure, while under 7 atm. (abs.) they were killed within 3 h. Death was considered to have occurred on cessation of ciliary motion and loss of pulsation of the contractile vacuole. Control animals observed in nitrogen–air mixtures for identical times appeared perfectly normal and, when removed to atmospheric air, remained so throughout a 3-week period of observation.

In the second series of experiments, following death by exposure to hyperbaric oxygen at the pressures and times already outlined, some dishes were returned to normal air while others were kept under pure oxygen for up to 3 weeks at lethal pressures.

Microscopic observations. All organisms were observed by a high-power long-working distance stereomicroscope (Zeiss) which permitted good resolution through the walls of the 'Lucite' pressure chamber. By this method, the time of death as evidenced by cessation of ciliary motion could be determined precisely. It was also possible to follow some aspects of the cytological condition of the protozoa subsequent to death. In all the oxygen-exposed dishes, no evidence of marked cytolysis was detected even after 2 weeks following death of the *Paramecia*, provided these remained under oxygen. The macronucleus, contractile vacuoles and some of the cytoplasmic inclusions ordinarily detectable under the phase-contrast microscope appeared intact. Food vacuoles were not present. Animals exposed to and maintained at 3 atm. (abs.) of oxygen until death showed some signs of cytolysis after 2 weeks; those dead from exposure to 7 atm. (abs.) of oxygen retained their essentially 'normal' appearance for at least an additional 3 weeks. Further details of the cytological alterations of these organisms, including cytochemical observations, are to be reported elsewhere.

Determination of proteolytic activity. We used a modification of the method of Anson[5] with dialysed bovine haemoglobin as substrate. For spectrophotometric determination, approximately 0·1 ml. portions of homogenized *Paramecia* (known number of organisms per unit volume) were added to 0·5 ml. of substrate (*p*H 2·5) at 37° C. At intervals, the reaction was stopped by addition of 1·0 ml. of 0·3 M trichloroacetic acid, centrifuged and the supernatant placed in a specially adapted microwell of a Beckman *DU* spectrophotometer at 280 mμ. Blanks consisted of 0·1 ml. homogenated organisms added directly

to 1·0 ml. 0·3 M trichloroacetic acid followed by 0·5 ml. of haemoglobin substrate. The percentage hydrolysis was calculated by the formula $100\ (E_t - E_0)/(E_\infty - E_0)$ where E_0 is the extinction coefficient of the blank, E_t is the extinction coefficient at time t and E_∞ is the extinction coefficient at complete digestion.

While other dynamics of the enzyme system encountered will be considered elsewhere, a distinct inhibition of catheptic activity by oxygen occurred. Fig. 1 shows the substrate hydrolysis obtained with incubation times up to 16 h. To demonstrate that pressure alone is not a factor, aliquots of homogenized *Paramecia* were exposed to 120 lb./in.^{2} (gauge pressure) using pure 99·8 per cent nitrogen in an unflushed vessel which would thereby contain a normal single atmosphere of air with its normal equivalent of oxygen. These results are also considered in Fig. 1.

Significant inhibition of hydrolysis by the enzyme system under investigation occurred with exposure to 120 lb./in.^{2} (abs.) of oxygen (26° C) during a 45 min exposure (Fig. 2). A 10-min exposure to similar concentrations of oxygen produced no detectable difference in the rate of enzymatic hydrolysis as compared with unexposed control animals killed by thermal shock (10 min exposure to 37° C, Fig. 1). The most marked inhibition of hydrolysis occurred with a 60-min exposure to 120 lb./in.^{2} of oxygen at 26° C (Fig. 2).

The ability of oxygen to inhibit catheptic activity may be dependent on temperature, but our present report deals with a single temperature. The temperature dependence of oxygen poisoning in protozoa was previously described[2], but quantitative data with respect to enzymatic activity have not been reported.

Previous investigations[6] on the effects of hyperbaric oxygen on amphibian embryos have indicated that a limited rate of autolysis occurs. Such an effect, especially apparent during specific early stages of development, could be separated from the oxygen-inhibitions of oxidative enzyme systems which were previously described in tissue homogenates[7–12].

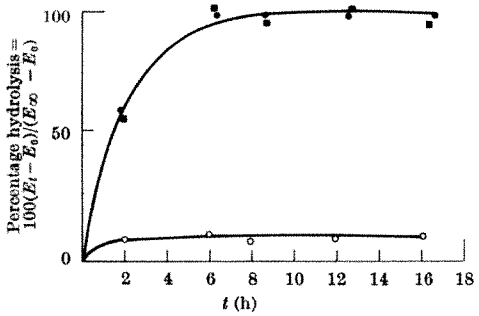

Fig. 1. Hydrolysis of haemoglobin substrate by homogenates of pooled *Paramecium caudatum*. Living organisms had been exposed to 120 lb./in.^{2} (abs.) oxygen (○), or to 105 lb./in.^{2} (gauge) + a single atmosphere of normal air (●), both for 60 min. An additional series consisted of animals killed by exposure to 37° C for 10 min (■). In each case aliquots consisted of 0·1 ml. of a homogenate from a pooled culture containing approximately 16,000 organisms per c.c. Exposure temperature was 26° C while under pressure

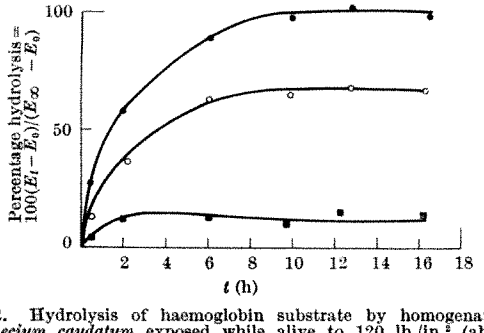

Fig. 2. Hydrolysis of haemoglobin substrate by homogenates of *Paramecium caudatum* exposed while alive to 120 lb./in.^{2} (abs.) of pure oxygen for: ●, 10 min; ○, 45 min; ■, 60 min. Exposure temperature was 26° C. Aliquots consisted of 0·1 ml. of a homogenate from a pooled culture containing 16,000 organisms per c.c.

The effects by hyperbaric oxygen on ontogenesis include production of teratogenic phenomena[13,14] and may reflect a significant role for some hydrolytic enzymes during development. Recently, hyperbaric oxygen has been shown to produce mammalian congenital malformations to some degree[15].

The effect of hyperbaric oxygen on limiting the rate of or totally inhibiting cell autolysis may reflect an inhibition of enzyme by inactivation of the sulphydryl co-factors on which some kinds of 'catheptic' activity are known to depend. However, it is also possible to evoke some recent concepts involving a possible cytochemical basis for control of cell death. In this respect, the subcellular lysosomes, first described as a biochemical entity in mammalian hepatic cells[17], could play a part. In a variety of cell types, these subcellular particles have been described as being composed of a single limiting membrane containing an assortment of hydrolases with acid *p*H optima[17]. The external limiting membrane, composed in great part of a lipoprotein complex, may become stabilized under the oxygen tensions used in the present investigation. Stability of the lysosomal membrane appears to be increased by at least two steroids, oestrogen[18] and hydrocortisone[19]. A stabilization of such a membrane by oxygen could either limit release of enzyme or prevent access of substrate to hydrolases compartmentalized with the subcellular unit. 'Cathepsin' has been described as one of a number of such contained enzymes[17]. However, a recent report[20] has suggested that the lysosomal membrane presents an increased permeability to high atmospheric oxygen concentrations. Furthermore, model lipid membranes appear to become readily oxidized by air and are then unstable[21], but these observations may not be comparable with an *in vivo* membrane system presumably being maintained by higher energy states. With these observations in mind, it is equally likely that in our experiments oxygen did not stabilize the lysosomal membrane but directly inactivated enzymatic protein.

The part played by oxygen in the preservation of mammalian tissue is at present being explored at the cellular level. It has been described, but the mechanism of action has not been explained, for the preservation of tissues for surgical transplantation[22]. It is not unreasonable that a primary action at the cell-level is a limitation of autolysis. Certainly, the effects of hyperbaric oxygen in inhibiting oxidative metabolism at the level of pyruvate oxidase and α-oxaloglutarate dehydrogenase, possibly through α-lipoic acid[11,16], would not permit us to conclude that an increased metabolism was the cause of such tissue preservation.

PLAQUE FORMATION BY PURIFIED SALIVARY MUCIN *IN VITRO*: EFFECTS OF INCUBATION, CALCIUM AND PHOSPHATE

By CHARLES McGAUGHEY and DR. ELLERY C. STOWELL
Dental Research Programme, Veterans Administration Hospital, Long Beach, California

DENTAL plaque, which has been defined in a general way as the insoluble organic material which is tightly bound to teeth[1], is implicated in the aetiology of dental caries and periodontal disease because of its content of oral pathogens. It can also become calcified to form salivary calculus which may cause gingivitis by mechanical irritation. Investigation of the origin of plaque thus assumes a high priority among the objectives of dental research.

There is evidence that altered forms of salivary mucin are constituents of plaque. The amino-acid spectrum of the organic matrix of salivary calculus has been found to be qualitatively and quantitatively similar to that of mucin, and there is a qualitative resemblance in the carbohydrate content[2]. Sialic acid[3] and fucose[4] are nearly absent and hexosamine is somewhat low[3] in plaque as compared with mucin, probably as a result of bacterial degradation. Material resembling plaque in its tinctorial properties has been found to result from incubation of precipitated salivary mucin in saliva[5]. The amino-acid spectrum of a certain type of plaque termed 'denture pellicle' has been observed[6] to be quite different from that of salivary mucin. It could, however, be a degradation product of mucin.

It has been suggested that surface denaturation[2], the loss of sialic acid[3], or local *p*H changes[2,7] cause the deposition of salivary mucin on teeth. The evidence is, however, circumstantial and it has not been shown that these changes do, in fact, enable the altered mucin to become attached to the tooth surface. In order to investigate this problem further, we have undertaken a systematic search for various environmental influences which will modify the mucin molecule sufficiently to permit binding to surfaces.

Purified porcine submaxillary mucin ('PSM', Sigma Chemical Co., St. Louis) was dissolved in distilled water (1–2 mg/ml., *p*H 6·7) and subjected to various experimental conditions. Aliquots were then added to depression slides with or without other additions and evaporated in a desiccator over sulphuric acid. The residues were washed twice with five-drop portions of water and the slides were allowed to dry. The material remaining bound to the glass was stained with Ponceau red (200 mg per cent in 5 per cent trichloroacetic acid (TCA)) (Gelman Instrument Co., Ann Arbor) and photographed using green transmitted light.

When aqueous solutions of 'PSM' (1 mg/ml.), either fresh or incubated at 38° C for periods up to 18 h, were treated as described above, no observable residues remained bound to the glass after washing (Fig. 1). If incubation was prolonged beyond 18 h, precipitation occurred in the incubation tube and the precipitate remaining on the slide after evaporation was not removed by washing.

When the 'PSM' was dissolved in water (2 mg/ml.) and an equal volume of sodium phosphate (0·01 M, *p*H 6·5) was added, bound residues always remained after washing, whether or not incubation had been carried out (Fig. 1). The residues from unincubated 'PSM' were more widely distributed over the glass surface, were more flaky, and were more easily washed away. With increased periods of incubation, the residues tended to become concentrated in rings around the periphery and were much more tightly bound; thus, when the number of washings was increased from two to four, the residues from fresh 'PSM' were usually washed away completely, whereas residual material was quite apparent from samples incubated 30 min or more. If incubation was prolonged for periods exceeding 18 h, precipitation occurred in the incubation

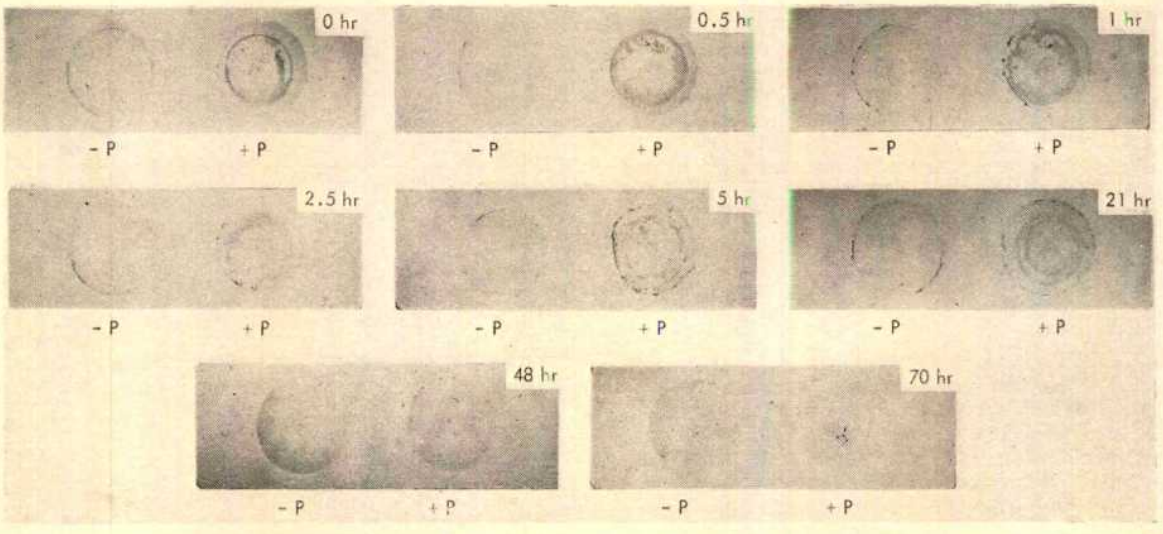

Fig. 1. Effects of phosphate and incubation on the formation of glass-bound residues by porcine submaxillary mucin. The mucin solution (1 mg/ml., *p*H 6·7) was incubated in the presence (+P) or absence (−P) of sodium phosphate (final concentration, 0·005 M) for the indicated periods of time. Aliquots (100 μl.) were evaporated on depression slides, washed, and stained as described in the text

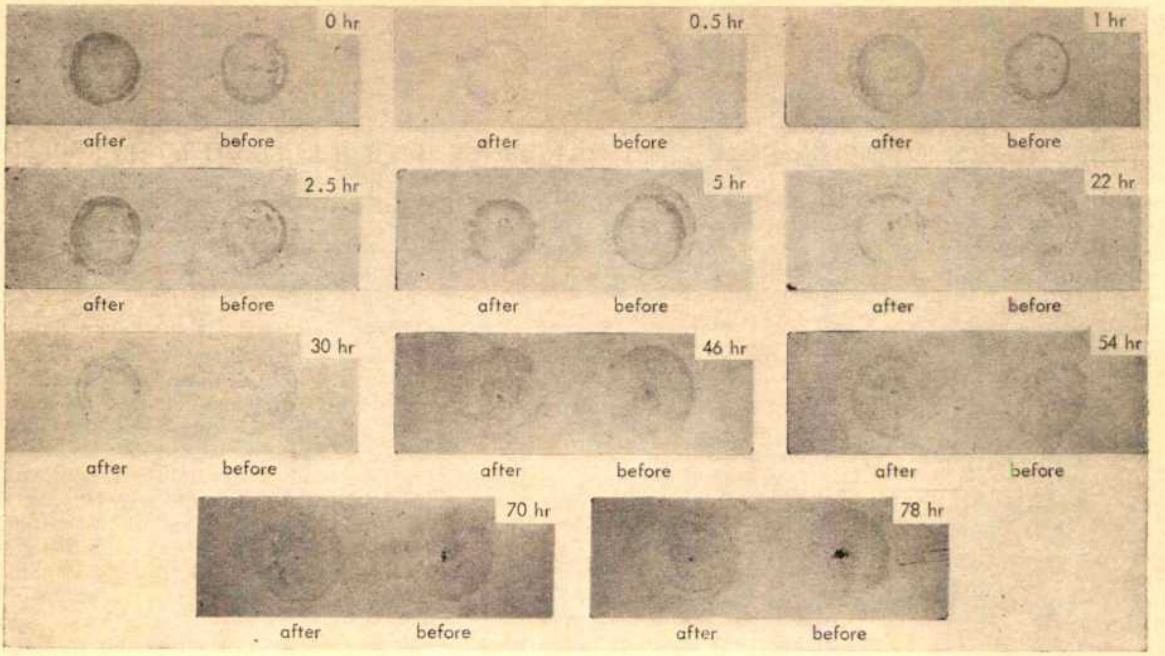

Fig. 2. Comparison of results obtained by adding phosphate before and after incubation of mucin. Where phosphate was added before incubation, the mucin concentration during incubation was 1 mg/ml., the phosphate concentration was 0·005 M, and 100 μl. were evaporated. Where phosphate was added after incubation, the mucin concentration during incubation was 2 mg/ml., and 50 μl. of mucin and 50 μl. of 0·01 M phosphate were evaporated. The amounts and concentrations of mucin and phosphate evaporated were thus kept constant. Evaporation, washing, and staining were carried out as described in the text. Incubation temperature, 38° C; *p*H, 6·7

tubes, but the precipitate coalesced into much larger particles than in the absence of phosphate. These particles settled to the bottom of the incubation tube where they adhered to the glass. In the absence of phosphate the precipitate did not adhere to the glass of the tube. The large particles which formed in the presence of phosphate remained bound to the glass slide after evaporation and washing (70 h incubation, Fig. 1). These observations clearly show that phosphate is necessary for the binding of difficulty soluble forms of porcine submaxillary mucin to a glass surface. It is of interest that after 48 h of incubation, the outer rings were quite apparent after washing with water, but were not visible after staining, having become soluble in TCA. By 70 h, the outer rings were not seen even before staining.

The residues obtained after incubation with phosphate were compared with those obtained when phosphate was added after incubation. Fig. 2 shows that the residues were similar; however, the residues from incubation with phosphate showed much more diffuse, granular material in the middle portion of the slides (not well shown in Fig. 2). Note that the coarse precipitate which had formed after 70 h of incubation with phosphate (centre of depression) was not present when phosphate was added after incubation. Also, there was often more TCA-insoluble material deposited as a thin layer by the latter samples at later incubation times. These results show that the material formed by incubation with phosphate has a nature somewhat different from that of the material formed by incubation followed by addition of phosphate. It is apparent that phosphate is not necessary for the formation of the organic material which binds to the glass, but only for the binding process.

The PSM preparation used contained 5·6 per cent calcium as determined by ethylenediamine tetraacetic acid (EDTA)–calcein titration (unpublished method, Uni-tech Corp., Panorama City, California), but only contained 1·4 per cent total phosphorus as determined by the method of Beveridge and Johnson[9]. It thus seemed possible that the added phosphate became attached to the mucin molecule at the sites of calcium binding. This was tested as follows: calcium was removed from a 10-ml. sample of 'PSM' (2 mg/ml. in water) by a single treatment with large excess of 'Dowex-50-X8' sodium ion-exchange resin (50 mg dry weight). An equal volume of sodium phosphate (0·01 M, *p*H 6·5) was added and incubation was carried out at 38° C for 30 min. Fig. 3 shows that no bound residue was formed by the sample from which calcium had been removed, but that an excellent residue was obtained from a sample to which the removed calcium had been restored. It was shown, by EDTA titration, that 93 per cent of the calcium had been removed from mucin by the resin treatment. These results indicate that the ability of phosphate to promote the formation of surface-bound residues from 'PSM' is dependent on the presence of calcium.

The foregoing results suggest a mechanism for the initial phase of the formation of dental plaque. We have formed the hypothesis that phosphate binds to salivary mucin at sites already possessing bound calcium. This process

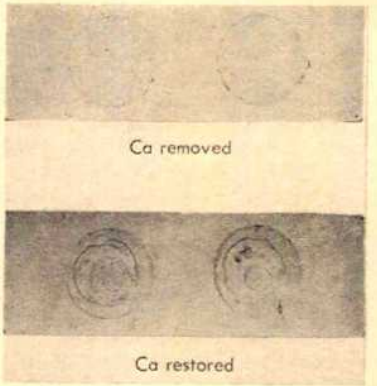

Fig. 3. Effects of removing and restoring calcium on the formation of glass-bound residues by porcine submaxillary mucin. Calcium was removed from the mucin with 'Dowex-50' ion-exchange resin. The solution was divided into two parts and the calcium was restored to one part by adding calcium chloride. Phosphate was added to both of the solutions and incubation was carried out for 30 min at 38° C, *p*H 6·7. Aliquots (100 μl.) were then evaporated, washed, and stained as described in the text. Mucin concentration during incubation, 1 mg/ml.; phosphate concentration, 0·005 M; calcium concentration, 0·0014 M

would form relatively insoluble materials which would adhere to the tooth surface on evaporation of the moisture from thin layers of saliva. It is possible also that bound calcium and phosphate facilitate the attachment of films of saliva to the tooth surface to form a relatively stationary medium capable of trapping oral bacteria. Incubation of the mucin in the oral environment causes its depolymerization, and when the product combines with phosphate the resulting material is less soluble and/or more adherent to surfaces than is the case with fresh mucin. The depolymerization probably involves hydrolysis of peptide bonds. This is supported not only by the formation of TCA-soluble residues in our experiments, but also by the work of Bettelheim[8] who observed the appearance of free carboxyl groups during incubation of bovine submaxillary mucin under mild conditions. Such material would be expected to have a chemical composition different from the original mucin, and this might account for the results of Smith[6], who has found that the amino-acid spectrum of 'denture pellicle' differs markedly from that of salivary mucin. Similar changes could, of course, also occur through bacterial degradation of the mucin[5]; however, bacterial contamination was probably not a factor in our experiments because the results were quite reproducible in all respects. If the mucin remains in the mouth for a sufficient period of time, precipitation of calcium- and phosphate-bound mucin product may occur and, as we suggest, this material would probably adhere to the tooth surface without evaporation.

In contrast with the results for 'PSM', treatment of whole human wax-stimulated saliva with 'Dowex-50' resin did not completely prevent, but only markedly inhibited, the binding of residues to glass surfaces. Experiments are planned to determine whether this resulted from incomplete removal of calcium or from the presence of materials which bind easily in the absence of calcium.

Eilberg, Gould and Sobel[10] have shown that an organic film can form on glass slides as a result of repeated incubation in and evaporation of calcium-free saliva. This film is calcifiable in the presence of calcium and phosphate. It would be of interest to determine whether the deposition of the film is facilitated by these ions.

Finally, the present results fit closely with those of Dawes and Jenkins[11], who have found that both calcium and phosphate are concentrated in plaque with respect to saliva. It would appear that such concentration may occur prior to, and indeed may facilitate, the deposition of the organic matrix of plaque. Calcium phosphate would thereby assume the hitherto unsuspected role of a deleterious 'biological cement'.

OBSERVATIONS ON THE BIONOMICS OF THE MARINE NEMATODE, *Metoncholaimus* SP.

By B. E. HOPPER and Prof. S. P. MEYERS

Entomology Research Institute, Canada Department of Agriculture, and Institute of Marine Science, University of Miami

COMPARATIVELY scant information exists on the bionomics of nematodes in the marine environment. In conjunction with our biological investigations of sea-grass communities (turtle grass, *Thalassia testudinum*, Konig) in Biscayne Bay (Miami), Florida[1], an undescribed species[2] of the genus *Metoncholaimus* was isolated in large concentrations during the autumn and winter of 1964–65 (ref. 3). At times, the animal comprised the dominant meiofaunal representative in the upper layers of the sediment. Patterns of activity of the species suggested the presence of environmental and biological factors affecting population dynamics as well as the extant ratios of the sexes. Data on various biological characteristics of the animal, including movement, egg deposition and development, are noted here.

Metoncholaimus sp. is a large (4 mm in length) and active animal with characteristic dorso-ventral undulatory movements both in sea water agar (0·5 per cent) and on fungal-cellulose mats. The head moves constantly in a probing manner, as if 'seeking food' or 'testing' the environment. Probably, this movement accomplishes both functions, for numerous sensory organs, labial papillae, cephalic setae and amphids are located at the head. (Disagreement exists on the function of the amphids. In general, the amphid is thought to be a chemo-receptive structure[4,5]. However, it has been suggested[6] that the amphids are mechano-stretch receptors in at least those groups of the Nematoda that possess weak cuticles. While neither hypothesis has been tested experimentally, the former one would appear more acceptable on a morphological/physiological basis.) A withdrawal reaction is noted when contact is made with a needle placed in the path of the nematode. Movement occurs readily in a forward or reverse direction. Frequently during migration on agar, *Metoncholaimus* sp. forms acute angles, resulting in the cuticle becoming twisted and wrinkled. These angles and wrinkles are transmitted down the animal as it passes through the agar. Gray and Lissmann[7] discuss locomotion of other nematodes and describe undulatory waves generated at the anterior portion which travel posteriorly the length of the body. The wave generated by *Metoncholaimus* sp. remains stationary as the nema migrates. The animal does not 'overstretch' on the outer side of the wave but does show an 'accordion-like' appearance on the inner surface.

Individual specimens in sea water apart from a substrate coil into irregularly shaped balls. Often the spinneret is used for attachment to the bottom of the glass dish with characteristic probing action. When many nemas are added to sea water in the same dish, rapid coiling and entwining occur, resembling a Medusa's head. When a cellulosic substrate is placed in the liquid in contact with an animal, the specimen usually uncoils and enters the substrate quickly.

Metoncholaimus sp. dropped into cylinders of sea water exhibit serpentine movements for a short time (<5 sec), quickly coil, and fall through the water column in this position with the anterior region probing. Probably,

their descent in samples with sand and other detritus would be more rapid due to adherence to particles. Striking differences are noted in the rate of fall between viable and freshly preserved specimens of *Metoncholaimus* sp. (Fig. 1). In tests conducted at room temperature the descent of specimens over a distance of 22 cm was recorded at 10 sec intervals. Fifty per cent of the viable animals fell within 60 sec, while 145 sec were required for an equal percentage of preserved nematodes to fall the same distance. Similar striking differences occurred at the 100 per cent level. In general, no differences in the rate of fall were observed between freshly preserved animals and those preserved for 5–10 days.

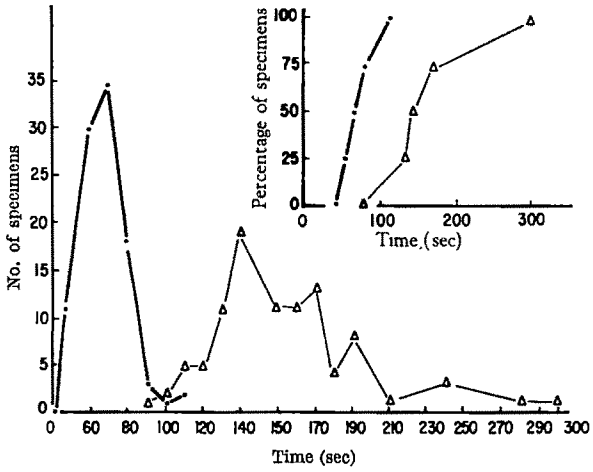

Fig. 1. Rate of fall of viable (•) and freshly preserved (Δ) specimens of *Metoncholaimus* sp.

Swarming or monospecific affinity has been reported for certain plant parasitic nematodes (*Helicotylenthus nannus, Tylenchorhynchus claytoni* and *Criconemoides* sp.) in water agar[6]. Rapid and random dispersal occurred in sea water agar, and in no instance was a monospecific attraction observed. Frequently, freshly collected fungal mats showed large concentrations of *Metoncholaimus* sp. with as many as several thousand gravid specimens on test substrates submerged for periods as short as 72 h. It has not been established whether this aggregation of gravid animals represents a swarming response, as already noted

Terrestrial nematodes differ from marine species in their ability to penetrate and colonize water agar. Marine nematodes do poorly on 1·7 per cent sea water agar (salinity 35 parts per thousand). In tests of various concentrations of agar, that is, 0·5, 1·0, 1·5 and 2·0 per cent, prepared with sea water, specimens of *Metoncholaimus* sp. most readily entered and moved within the 0·5 per cent agar medium. In the latter, specimens have often been observed to travel a distance equal to their body length of 4 mm in less than 30 sec. The 1·0 and 1·5 per cent agars permitted slight penetration of a few specimens, while no penetration and only surface migration occurred in the 2·0 per cent medium. In addition to ease of penetration, the nematodes remained active for a longer period in the 0·5 per cent agar. This latter concentration was used for the majority of our observations on *Metoncholaimus* sp.

Egg deposition. Females commonly carry between 5 and 20 eggs in their uterus, although as many as 51 eggs were counted in one specimen. At deposition, eggs are released in rapid succession, resulting in the formation of egg clusters or packets. Occasionally, single eggs are retained in the uterus after the main mass has been deposited. Death of the female appears to follow egg deposition. Subsequent development of eggs was not observed. Number of eggs in the clusters is comparable to amounts found in the uterus; however, single eggs occasionally are seen.

Clusters of 10 to 20 eggs frequently are observed on fungal cellulose mats. The eggs have a gelatinous coating and adhere together both in agar and on the fungal mat.

Frequently, eggs are deposited within the initial 24 h on sea water agar. In a comparison of egg deposition at 15°, 20° and 25° C, greater egg release occurred at 15° C. Often, eggs were deposited during the short time required for microscopic observation of the 15° C sea water agar plate. The temperature change from 15° C to room temperature during examination may stimulate deposition.

Eggs are deposited unsegmented and undergo several cell divisions during the initial 8 h. In tests in sea water agar and liquid, in the light (25° C) and dark (18° C), with and without agitation, eggs often hatched within six days. Occasionally, hatching may require 8–10 days. Once released, juveniles increase rapidly in length on the sea water agar.

Feeding and development. Limited observations have been made on the feeding of *Metoncholaimus* sp. Animals survive for as long as several months in sea water flasks containing a fungal-cellulose substrate. Adults are able to feed on marine bacteria and yeasts in liquid culture. In agar, juveniles were found ingesting ciliates which had developed adjacent to a dead adult. This feeding was associated with a decrease in the number of ciliates with a concurrent increase in the size of the juveniles. Furthermore, the intestinal coloration was different (darker) from that noted for the non-feeding animals.

Attempts to culture *Metoncholaimus* sp. on the stylet-bearing nematode, *Aphelenchoides* sp., were unsuccessful. In one instance, gravid *Metoncholaimus* sp. fed on the contents of their own broken eggs, whereas adjacent intact eggs remained undisturbed.

Metoncholaimus sp. occasionally swallows air bubbles, often at a rapid rate. The bubbles pass quickly through the oesophagus to the anterior portion of the intestine, where they accumulate. Subsequently, these move posteriorly, decreasing in size, until they are completely absorbed at a distance 1/2 to 2/3 from the anterior end of the intestine.

Both adults and juveniles are active in sea water agar for several weeks, after which the nemas are attacked by bacteria developing in the medium. In one test, *Metoncholaimus* sp. and *Euchromadora* sp. were placed in agar media, following which bacteria attacked the latter animals, decomposing the softer parts of the body and leaving the harder components of the cuticle as 'rows of hoops' through the agar. The bacteria have been identified tentatively as species of *Pseudomonas, Vibrio* and *Agrobacterium*. Initially, *Metoncholaimus* sp. showed resistance to bacterial activity, but after several weeks was also attacked.

Field and laboratory investigations are being continued to determine the life cycle and role of this species in the environment. Present data, based on hatching time, development of juveniles, and seasonal concentration of gravid females, suggest a cycle shorter than one year.

This work was supported by grant *GM* 12842 from the National Institutes of Health to the Marine Laboratory, Institute of Marine Science, University of Miami.

ASTROPHYSICS

Early Radiation Field and High-energy Electrons in Supernovae

THE discovery of an X-ray source associated with the Crab Nebula[1,2] has prompted an intensive search for X-ray sources associated with other known Type I supernovae, for example, Tycho, and Kepler[3,4]. So far this search has proved fruitless. One is thus led to wonder what essential differences between supernovae of the same type might result in the presence or absence of X-ray emission. Morrison and Sartori[5] have proposed a thermal radiation model to account for this discrepancy. On the other hand, Woltjer[6] has argued that the observed X-ray emission from the Crab Nebula is due to synchrotron radiation. I suggest that if Woltjer's hypothesis is correct, a critical part is played by the intensity of the early post-explosion radiation field; for this field, by way of the inverse Compton effect, limits the energy of the electrons in the supernova. In fact, I estimate that no extreme relativistic electrons ($E > 10^{12}$ eV) can survive the first few weeks after the explosion. The situation is somewhat similar to that which gives rise to an upper bound on the energy of cosmic-ray electrons—the inverse Compton effect from starlight and synchrotron radiation in the galactic magnetic fields forcing a limit on the electron energy[7].

To make my point, I shall discuss a concrete example, namely, the Crab Nebula. Let us take, for the sake of argument, a simple model in which we assume that the currently observed X-ray emission is due to synchrotron radiation by a relatively small number of nearly monoenergetic high-energy electrons trapped in a weak magnetic field. The radiating electrons are assumed not to be significantly accelerated at the present time. Typical parameters appropriate to the foregoing assumptions and consistent with the observed X-ray fluxes from the Crab Nebula are given in Table 1.

Table 1

Half-life	$\gtrsim 10^3$ years
Frequency of X-radiation	$\gtrsim 10^{18}$ c/s
Present electron energy	$\gtrsim 10^{14}$ eV
Magnetic field*	$\gtrsim 10^{-3}$ gauss
Initial energy stored in X-radiating electrons	$\gtrsim 10^{44}$ ergs

* This magnetic field is about one-tenth that normally accepted for the average field of the Crab Nebula. However, consistent with the observations, this smaller field need occupy only a small fraction of the volume of the Nebula. Note that even smaller local fields are necessary to account for recent observations of localized radio-frequency emissions from the Crab Nebula[8].

Recently, Jones[9] has computed the electron energy loss rate due to inverse Compton effect in radiation fields up to 10^4 °K. This corresponds to the radiation energy density ($\simeq 75$ ergs/cm^3) about 10 days after the explosion of the Type I supernova (radiant energy input of about 10^{50} ergs)—it being assumed that the dilution of the radiation field is unimpeded by interstellar matter, and thus, that the radius of the sphere containing the radiation grows nearly at the velocity of light. Jones has shown that in an equilibrium radiation field the electron energy loss rate due to inverse Compton effect is:

$$-\mathrm{d}E/\mathrm{d}t \simeq 2{\cdot}5 \times 10^{-25}\, c\rho \mathrm{F}(E,T) \text{ ergs/sec}$$

where c is the velocity of light; ρ, the energy density in the radiation field (αT^4); E, the electron energy; T, the black-body temperature of the radiation field. All quantities are in C.G.S. units.

The function $\mathrm{F}(E, T)$ is proportional to E^2 for $E \lesssim 10^{10}$ eV, and increases logarithmically for higher electron energies. For electrons with energies in excess of about 2×10^{12} eV and radiation density corresponding to $T \sim 10^4$ °K, we find from Jones's calculation that:

$$\mathrm{F}(E, T) \simeq 10^{12}$$

These electrons will then lose energy at the rate of 4×10^{11} eV/sec. Therefore, the time required for an electron starting with energy E_i to be degraded to a final energy $E_f \simeq 2 \times 10^{12}$ eV is approximately:

$$\Delta t \simeq 2{\cdot}5 \times 10^{-12} E_i \text{ sec}$$

where E_i is in eV.

It is easily seen, then, that if we can characterize the early radiation field in a supernova by an equivalent black-body temperature, electrons with initial energies less than about 4×10^{17} eV will have decreased their energy to 2×10^{12} eV during the first 10 days. But electrons accelerated after some further dilution of the radiation field has occurred may survive with energies sufficiently large to participate in the currently observed X-ray emission. In order for the electrons to retain energy of about 10^{14} eV at the end of a few weeks (as required by our model), their initial energy would have to exceed 10^{20} eV. But then the energy initially acquired by those electrons would exceed the total estimated energy released in the supernova.

Thus, because of the energy requirements, the initial electron acceleration process must have been effective for a time sufficiently long for the radiation field to have been diluted so that electrons with energies $\simeq 10^{14}$ eV did not promptly lose a significant fraction of their energy by the inverse Compton effect.

As seen in the foregoing, in the energy range under consideration losses by inverse Compton effect depend only logarithmically on the electron energy. Thus, the emergent electron energy depends in a weak, albeit non-negligible, manner on initial injection energy. This is unlike the case of losses by synchrotron radiation which depend quadratically on the electron energy.

It is worth mentioning here that, in addition to the limitations on electron energies imposed by the inverse Compton effect, the possible presence of magnetic fields during the early stages of the supernova expansion further limits the efficiency of potential electron acceleration mechanisms. Thus, as is easily shown, an electron injected with an extreme relativistic energy, E_i, traversing a region of typical dimensions R cm containing a magnetic field with energy density $H^2/8\pi$ will emerge with a final energy:

$$E_f \simeq 10^{24}/(RH^2)\text{eV for } E_i \gg E_f$$

Thus we are led to speculate that the absence of sufficiently high-energy electrons, and hence of observable X-rays from Tycho and Kepler, may be due to unfavourable relative phasing of the dilution of the radiation field, the growth of the, as yet, undefined acceleration mechanism, and of the prevailing magnetic field. For as already shown, no significant number of electrons can retain high energies in the face of the initial radiation field of the supernova.

Pending detailed calculations, as well as additional data, it is still an open question whether a favourable relative phasing is at all feasible; or if a continuous but unspecified acceleration mechanism, such as that postulated *ad hoc* by Parker[10] for magneto-active plasmas, is necessary to explain the observation of X-ray emission or lack thereof.

I thank B. Rossi and P. Morrison, of the Massachusetts Institute of Technology, and M. Annis and J. W. Carpenter, of American Science and Engineering, for advice.

PHYSICS

Intensity Distribution of the Lyman–Birge–Hopfield Band System of N_2

Recent rocket investigations of the vacuum ultraviolet radiation emitted from the aurora and airglow have shown up the need for laboratory measurements of molecular band intensities in this spectral region. Such laboratory investigations have until now been hampered by a lack of suitable intensity standards. One prominent band system of importance in this region is the Lyman–Birge–Hopfield (LBH) ($a\ ^1\Pi_g - X\ ^1\Sigma_g^+$) system of N_2, which lies between 2000 Å and 1200 Å. It has recently been observed in auroral spectra taken by rocket-borne spectrometers[1,2]. The only laboratory measurements of intensities of bands of the LBH system in emission are estimates of photographic plate blackenings[3], where no account has been taken of variation of instrumental response with wave-length.

Franck–Condon factors $q_{v'v''}$ have recently been calculated for this band system[4] using realistic Rydberg–Klein–Rees potentials. These can be used together with measured band intensities $I_{v'v''}$ to determine the variation of the electronic transition moment $Re(r)$ over the band system and thereby to provide band strengths $S_{v'v''}$, since:

$$\left.\begin{aligned} I_{v'v''} &= K\, N_{v'}\, \nu^4\, R_e^2(\bar{r}_{v'v''})\, q_{v'v''}; \\ S_{v'v''} &= R_e^2\,(\bar{r}_{v'v''})\, q_{v'v''} \end{aligned}\right\} \qquad (1)$$

where K is a constant including units and geometry, $N_{v'}$ is the population of the upper state, and ν is the frequency of the band and $\bar{r}_{v'v''}$ is the r-centroid of the band. $R_e(r)$, the electronic transition moment, is assumed to be a smoothly varying function of internuclear separation.

This communication reports the results of relative intensity measurements of fifty of the major bands of the LBH system excited in a high-voltage a.c. discharge through nitrogen. A Hilger 3 m vacuum spectrograph with a photoelectric detector was used and the relative sensitivity of the instrument as a function of wave-length was established using a combination of standards including a carbon arc and a number of atomic lines the intensities of which could be calculated. Details of the calibration techniques will shortly be published.

From (1) it is seen that a plot of

$$\left(\frac{I}{q\nu^4\ N_{v'}}\right)^{\frac{1}{2}}_{v'v''}$$

versus $\bar{r}_{v'v''}$ or wave-length (to which it is monotomically related[5]) for each band delineates the variation of $R_e(r)$ over the band system. This plot was made for bands from the first four levels of the upper state ($v' = 0$ to 3) with the appropriate Franck–Condon factors[4] and population factors determined by inspection of the relative separation between the plots of $(I/q\nu^4)^{\frac{1}{2}}$ versus $\bar{r}$ for $v' = 0, 1, 2, 3$. No significant variation of $R_e(r)$ over the band system was observed. Hence to within the accuracy of the intensity measurements ($\pm$ 20 per cent) the electronic transition moment can be considered constant over the LBH system, and thus the calculated Franck–Condon factors directly indicate the relative band strengths. This conclusion had previously been tentatively suggested from an empirical observation on eye estimates of photographic blackening[6]. It is of considerable significance in identifying LBH bands in the spectra of such sources as the aurora and in determining source conditions.

Simplified Bulb Tracer System for Argon Analyses

This communication describes a simplified and inexpensive bulb-tracer system used for argon analyses in the potassium–argon age-determination laboratory of the United States Geological Survey. The system is easy to build and operate, and is portable. The cost of the tracer system, including the argon-38, is less than 50.00 dollars, so the unit cost per tracer is low. In the past year we have made more than 300 tracers, and we expect to make at least 300 more before refilling the bulb.

The tracer system (Fig. 1) consists of three 2-mm bore mercury-seal stopcocks connected to a 2-l. 'Pyrex' boiling flask. The gas pipette, D, is the volume between control stopcocks B and C. Stopcock A is a safety stopcock that allows the system to be removed from a vacuum line without exposing stopcock B to the atmosphere. The stopcocks are greased with high-vacuum silicone grease, which has a vapour pressure of about 10^{-7} mm Hg, to which we have added a very small amount of molybdenum sulphide. The molybdenum sulphide helps to prevent the

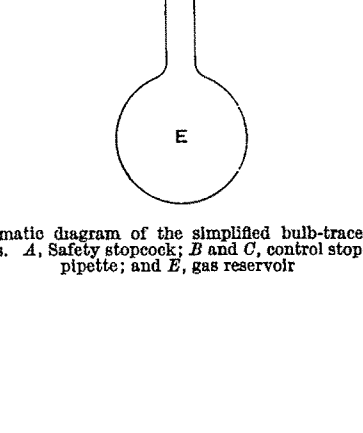

Fig. 1. Schematic diagram of the simplified bulb-tracer system for argon analyses. *A*, Safety stopcock; *B* and *C*, control stopcocks; *D*, gas pipette; and *E*, gas reservoir

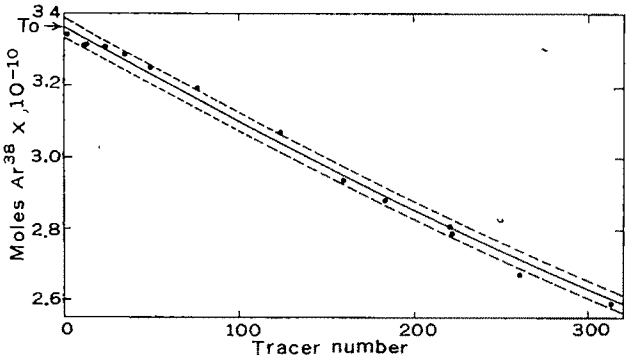

Fig. 2. Analyses of an intralaboratory standard mineral relative to the calculated depletion curve (solid line) for the simplified bulb-tracer system. The broken lines are 1 per cent above and below the calculated depletion curve

stopcocks from 'freezing up' with time. The apparatus is constructed inside a wooden case so that the system can easily be moved or stored when it is not in use.

The volume of the gas pipette, V_D, was determined by weighing the amount of mercury required to fill the pipette, and the volume of the gas reservoir, V_E, was determined by weighing it empty and full of water. The uncertainty in these measured volumes is about $\pm$ 0·1 per cent (standard error of the mean). The depletion, λ, of the reservoir per tracer release is given by:

$$\lambda = \frac{V_D}{V_E + V_D}$$

which for our system is equal to $0{\cdot}826 \times 10^{-3}$.

The amount of argon-38 in any given tracer, T_x, is found from:

$$T_x = T_0 \exp(-\lambda x) \qquad (1)$$

where T_0 is a constant and x is the tracer number (that is, if the tracer is the one hundred and forty-fifth one taken from the bulb, $x = 145$). T_0 is the mean of several values of T_0', which are calculated from formula (1) using experimentally determined values of T_x. These experimentally determined values of T_x are found by calibrating several individual tracers either by comparing them with a volume of atmospheric argon measured with a McLeod gauge or by comparing them with a known inter- or intra-laboratory standard mineral.

For routine operation we attach the tracer system to an ultra-high vacuum line that has two bakeable metal valves between the tracer and the pumping systems. Tracers are collected in individual tubes that consist of a breakseal tip and a side-arm containing activated charcoal. About twenty-five of these tubes are attached to the vacuum line at a time between the tracer system and the two valves, and the entire system, exclusive of the tracer system itself, is baked overnight at 300° C. An ionization gauge between the valves is used for measuring pressure after bakeout and for checking leaks.

If the system is vacuum-tight, the tracers are prepared in the following way. With stopcock B and the valves closed, stopcock C is opened and the gas pipette D and reservoir E are allowed to equilibrate for 20 min. Then C is closed, B is opened, and the argon in the pipette is adsorbed on a charcoal side-arm of a tracer tube cooled with liquid nitrogen. After collecting the argon for 30 min, the tracer tube is sealed off, the valve to the pumping system is opened, and the manifold and gas pipette are pumped for 10 min. The procedure is repeated for each tracer. Pressure measurements made with an ionization gauge indicate that more than 99·9 per cent of a prepared tracer is collected by this procedure. The results of tracer calibrations also indicate that quantitative collection of each tracer is obtained.

The tracer system may also be directly attached to the argon extraction line and a tracer prepared at the time of each experiment, but the procedure described here enables us to prepare and calibrate tracers before they are used in isotope dilution analyses. Should an accident occur to the tracer system between calibrations, no data are lost.

Plotted on Fig. 2, to illustrate the consistent behaviour of the tracer system, are fourteen analyses of a biotite that we use for an intra-laboratory standard. We analyse this biotite at least once in every fifty tracer releases in order to check for any relative changes in tracer concentration other than normal depletion. The standard deviation of these fourteen determinations is 0·6 per cent (relative to the calculated depletion curve) and represents not just the error contributed by the bulb-tracer system but the net result of all the errors involved in an isotope dilution determination of the quantity of radiogenic argon in a mineral. Our experience with a variety of bulb and manifold tracer systems indicates that this simplified system is as precise as any known system.

A Peak in the Tritium Content of Atmospheric Hydrogen following the Accident at Windscale

IN October 1957 Gonsior and Friedman[1] observed a strong peak in the tritium content of molecular hydrogen for air samples taken at Hamburg, Germany. They attributed this peak to the direct admixture of tritiated hydrogen produced on October 7, 1957, by a large thermonuclear explosion in the U.S.S.R. However, the mean monthly concentration of long-lived fission products in surface air showed no unusual increase during October 1957 (ref. 2). Additionally, no other such peaks have been observed to occur following the other thermonuclear test explosions during that period.

In view of the time of onset and the brief duration of the tritium peak it seems far more likely that the tritiated

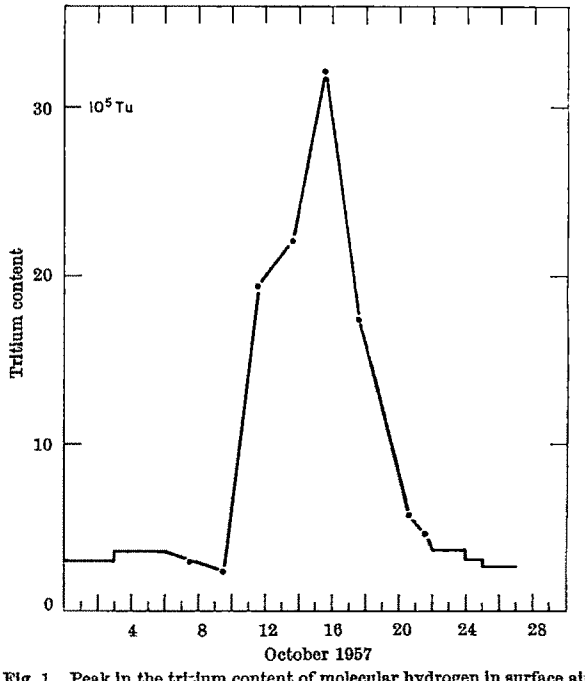

Fig. 1. Peak in the tritium content of molecular hydrogen in surface air during October 1957. The samples were taken at Hamburg and measured by Gonsior[1] (comp. his Table 1, samples 11–23)

hydrogen was released during the reactor accident at Windscale on October 10 and 11, 1957. Since the samples were taken two days apart, the initial rise in Fig. 1 is not well defined, but obviously the increase began either on October 11 or on October 12. The final rise to full maximum occurred between October 14 and 16. Thereafter the tritium content dropped steadily to its former value, which was reached about October 23.

This peak in tritiated hydrogen coincides well with the mixing pattern observed for the radioactive cloud injected by the Windscale accident, as illustrated by the distribution of the Windscale iodine-131 activity in air. From Figs. 3, 4 and 5 of the paper by Crabtree[3], it can be seen that the cloud arrived in the vicinity of Hamburg on about October 12 and extended farther north-east on subsequent days, giving rise to a continuous increase of the iodine-131 activity in air at Hamburg. No data were reported after October 15. By October 15 the horizontal gradient of the iodine-131 activity was already so small that subsequent horizontal and vertical mixing would be expected to cause a dilution rather than a further increase of activity.

The total amount of tritium released in the form of tritiated hydrogen cannot be estimated but cannot have contributed significantly to the global inventory of tritiated hydrogen, considering that the tritium concentration returned to its former value within 8 days.

Part of the released tritium must have been produced by ternary fission. A production of 0·8 tritium atoms per 10^4 fissions has been reported[4]. Another source is the reaction $^6Li(n\ \alpha)T$, due to irradiation of cartridges containing lithium–magnesium alloy which were present in the pile[5].

METEOROLOGY

Estimating Severity of Drought

In central Australia, the red kangaroo, *Megaleia rufa* (Desmarest), breeds continuously during favourable weather when the green herbage, which it prefers to eat[1,2], is abundant; but progressively more and more females become anoestrous during prolonged drought[2–4].

Pastures inhibited by drought respond to falls of rain ranging from about 1·16 in. in January to about 0·29 in. in July, and they respond well should enough rain fall later to keep the soil moist for about 4 weeks[5]. Since water evaporates from the soil about 0·2 times as fast as from a standard evaporimeter, an extra 2·31 in. of rain is needed in January and about 0·58 in. in July[5]. But the climate of the area is arid, the mean annual rainfall and evaporation at Alice Springs being 9·93 in. and 95·18 in. respectively. Therefore, adequate rain to stimulate general growth of pastures is uncommon, and droughts are frequent and often prolonged.

In order to compare droughts in different places and at different times during the course of the investigation of red kangaroos, a formal method of measuring the severity of a drought was needed. The 'drought index' described here served this purpose quite well.

When rain sufficient to cause pastures to respond fell in any month, the index was set to zero. The estimated rate at which moisture evaporates from the soil was then subtracted day by day from the amount of rain that fell, until the remainder reached zero. Throughout that period of time the drought index was kept at zero, that is, any drought experienced in that time was considered to be ineffective. Thereafter, the estimated evaporation from the soil was accumulated day by day to provide a measure of the aridity of a given period. If any rain falling in that time was insufficient to cause a general response in pastures, then the amount falling was subtracted from the index on the day it fell. But, if the rain falling was sufficient, then the index reverted to zero. It was found that the periods during which the index was set at zero corresponded well with the periods during which green herbage was abundant in the countryside. Because the index made allowance for the average drying power of each day in each month, it provided a quantitative estimate of the stress imposed on the physiology of plants, and of animals grazing them.

When the proportions of anoestrous female kangaroos and of the pouch-young which die in the pouch were plotted against the values of the drought index, *S*-shaped curves resulted[6]. This is the classic response obtained when groups of animals are experimentally exposed to increasing doses of a drug, and the appropriate model for testing this response is the probit analysis[7], which transforms such data so that a linear regression results. Probit analyses of the data for the kangaroos proved to be quite satisfactory. They showed that kangaroos on two areas of central Australia, separated by only 15–20 miles, responded differently ($P < 0{\cdot}05$) to droughts of the same severity, thus highlighting the different nature of the two areas, as one area was better grassed than the other[8].

The drought index, calculated in this manner, is therefore likely to be a sensitive way of describing the prevailing weather. It would do so more accurately if the actual evaporation of any day or month were to be used instead of the average, but none the less it seems quite satisfactory.

This method of describing the weather is an improvement on older methods which used the ratio of rainfall to evaporation, or some function of it[8–12], because it has a biological foundation (the response of native pastures), allows for the effectiveness of individual falls of rain and the severity of individual droughts, and offers a continuous record from day to day.

GEOLOGY

Allometric Growth of Ammonoid Shells : a Generalization of the Logarithmic Spiral

The fact that in many ammonoids the shape of the shell is only approximately represented by a logarithmic or equi-angular spiral curve is now fairly well known[1–4]. From the work of Currie[4], it is clear that the spiral angle of the curve traced by the umbilical seam in two species of *Cadoceras* undergoes changes during growth which have a fairly complicated pattern, so that a single continuous mathematical function may not fit any better than would two or more equi-angular spirals having different values of the spiral angle (φ). Moreover, the proportions of the cameral cross-section may vary during growth, with the result that the venter and the umbilical seam will follow different spiral curves. Also, in many ammonoids there

are rather clearly marked discontinuities in growth after the first or second complete whorl, and again at the commencement of the body-chamber.

Nevertheless, it may be useful to set out some results relating to the type of spiral curve to be expected when the Huxley–Teissier law is obeyed by the growth of the shell radius (R) and peripheral length (P), that is:

$$P = \beta R^{\alpha} \qquad (1)$$

If the proportions of the cameral cross-section remain constant, a similar relation will hold between the radius and the shell volume. Thus, Trueman[2] found that in *Dactylioceras commune* the volume of the shell is proportional to the diameter raised to the power 2·7. If we denote the cross-sectional area of a camera by A, it follows from our assumption that A is proportional to R^2. Then the volume V is given by.

$$V = \int A\,dP = k\int R^2 dP$$

From (1) we have:

$$dP = \alpha\beta R^{\alpha-1}dR$$

and therefore:

$$V = \alpha\beta k\int R^{\alpha+1}dR$$

whence we get.

$$V = \frac{\alpha\beta k}{\alpha+2}R^{\alpha+2} + \text{const.} \qquad (2)$$

The shell volume is thus proportional to the diameter (or radius) raised to the power $\alpha + 2$. We conclude that the spiral curve traced by, say, the venter of *D. commune* is that given by equation (1), with allometric index α approximately equal to 2·7 − 2 = 0·7.

It is not very convenient to measure the peripheral length directly on the shell of an ammonite. What we need is an equation relating the radius to the semi-whorl number: in other words, to the angle θ swept by the radius vector. I have shown elsewhere[5] that the polar equation can be derived by straightforward methods, by making use of the fact that $dP/dR = \sec\varphi$. We obtain:

$$\theta = \frac{1}{\alpha-1}(\tan\varphi - \varphi) + \text{const.} \qquad (3)$$

When $\alpha = 1$, $\sec\varphi$ is constant, and we then have:

$$\theta = \tan\varphi.\log R + \text{const.} \qquad (4)$$

which is the familiar result for the equi-angular spiral. Expressing (3) in terms of R instead of φ gives:

$$\theta = \frac{1}{\alpha-1}[\{(\alpha\beta R^{\alpha-1})^2 - 1\}^{1/2} - \text{arcsec}\,(\alpha\beta R^{\alpha-1})] + \text{const.} \qquad (5)$$

Suppose our data consist of a series of measurements of the radii of consecutive semi-whorls of the shell, that is, values of R at constant increments of θ equal to 180°. If we assume φ to be approximately constant over the interval $\theta_3 - \theta_1 = 2\pi$, then from equation (4) we obtain:

$$\tan\varphi_2 = \frac{2\pi}{\log\left(\frac{R_3}{R_1}\right)} \qquad (6)$$

at $R = R_2$. If we compute consecutive values of $(\tan\varphi - \varphi)$, and plot them against corresponding values of θ, then from equation (3) we may expect to find that the points lie on a straight line having slope $(\alpha - 1)$.

This procedure will thus yield an estimate of the value of α. To complete the process of curve fitting, we have to find the value of β, and also to find the value of a 'nuisance' parameter θ_0, which is the arbitrary constant in equations (3), (4) and (5). One method of estimating β is the following. For the jth measured point on the spiral, compute the geometric mean of R_{j-1}, R_j, and R_{j+1}. (We are assuming that over a short portion of the curve the trend of log R is linear.) We also find the arithmetic mean of a group of values of $(\tan\varphi - \varphi)$ centred on the jth point, and from it find the 'smoothed' value of φ_j from a table of arctangents. We can then compute β from the relation $\sec\varphi = \alpha\beta R^{\alpha-1}$. The process may be repeated at other points on the curve, and the individual values of β averaged. They should not show any systematic trend of increase or decrease: if they do, the allometric growth model may not be appropriate.

Finally, from (3) we obtain:

$$\theta_0 = \theta - \frac{1}{\alpha-1}(\tan\varphi - \varphi) \qquad (7)$$

In order to 'predict' values of R for specified θ, given the values of the parameters α, β and θ_0, we may re-arrange equations (5) and (7) as follows:

$$R = (\alpha\beta)^{1/(1-\alpha)}[\{(\theta - \theta_0)(\alpha - 1) + \varphi\}^2 + 1]^{1/2(\alpha-1)} \qquad (8)$$

We have to take an assumed value of φ in order to compute R from the foregoing expression, and if necessary iterate once or twice, correcting φ from the value of R obtained. In practice this is not a serious inconvenience, as convergence is rapid.

It follows from the foregoing results that when α is less than unity, φ decreases as R increases, and finally becomes zero at a finite value of R given by:

$$R_{\max} = \alpha\beta^{1/1(1-\alpha)}$$

There is thus a distinct possibility that the uncoiling that occurs in the final growth stages of certain ammonoids might indeed be the direct consequence of allometric growth (Thompson[1], p. 809).

The curve fitting process may be illustrated with an example of some data quoted by Thompson (*ibid.*, p. 797) for the shell of *Arcestes tornatus*. Thompson has already computed 'instantaneous' values of φ at successive semi-whorls of the shell, and we can proceed at once to plot θ against $(\tan\varphi - \varphi)$. (Values of θ and φ must, of course, be in radians.) The points lie on a more or less straight line with the exception of the first one (at R = 0·30 mm). As explained earlier, we would expect some deviation at the extremes of early and late growth; it is probably best in this case to exclude the first point from the fitting process. Since θ is virtually error-free, it would be appropriate to compute the regression of $(\tan\varphi - \varphi)$ on θ: however, the first-moment method due to Wald[6] is much quicker and is reasonably efficient[7]. The data are shown in Table 1.

Table 1. ALLOMETRIC GROWTH IN *Arcestes tornatus*

Semi-whorl number (θ/π)	Shell radius, (R) (mm)	Spiral angle, φ	Values of $(\tan\varphi - \varphi)$	Computed values of R (mm)
1	0·25			0·213
2	0·30	86° 56′	17·149	0 291
3	0 35	85 21	10·805	0·378
4	0·50	83 42	7·597	0·509
5	0·70	83 42	7·597	0·708
6	1·00	83 42	7·597	0·995
7	1·40	83 16	7·017	1·41
8	2·10	82 56	6·620	2·06
9	3 05	82 42	6·363	3·05
10	4·70	81 44	5·457	4·65
11	7·60	81 27	5·230	7·28
12	12·10	81 33	5·308	11·6
13	19·35			19 5

The data, consisting of measured shell radii and computed 'instantaneous' spiral angles, are from Thompson, p. 797, quoted from A. H. Grabau. The computed shell radii in the right-hand column are for a spiral curve having allometric index 0 8519, scale parameter 10·74, and location constant 70·55 (radians).

We divide the measurements into two groups, (1) for which $3\pi \leqslant \theta \leqslant 7\pi$, and (2) for which $8\pi \leqslant \theta \leqslant 12\pi$.

(1) Mean $\theta = 5\pi = 15{\cdot}708$; mean $(\tan\varphi - \varphi) = 8{\cdot}1226$, whence $\varphi = 1{\cdot}466$, $\cos\varphi = 0{\cdot}1046$; $R = 0{\cdot}7047$ (geometric mean of three values).

(2) Mean $\theta = 10\pi = 31{\cdot}416$; mean $(\tan\varphi - \varphi) = 5{\cdot}7956$, $\varphi = 1{\cdot}434$, $\cos\varphi = 0{\cdot}1364$; $R = 4{\cdot}776$ (geometric mean of three values).

We thus have:

$$\alpha - 1 = \frac{5{\cdot}7956 - 8{\cdot}1226}{31{\cdot}416 - 15{\cdot}708} = -0{\cdot}1481$$

$$\alpha = 0{\cdot}8519$$

For the first group, the estimate of β is given by:

$$\beta = \frac{(0{\cdot}7047)^{0.1481}}{0{\cdot}8519 \times 0{\cdot}1046} = 10{\cdot}66$$

and for the second group, β is found similarly to be 10·86: the mean of the two values is thus 10·76.

Finally, we have:

$$\theta_0 = \tfrac{1}{2}[15{\cdot}708 + 31{\cdot}416 + (8{\cdot}1223 + 5{\cdot}7956)/0{\cdot}1481] = 70{\cdot}55$$

In the right-hand column of Table 1 are shown the 'predicted' values of R computed from equation (8), inserting the foregoing values of α, β and θ_0. The fit is reasonably good, even at the extremes of the range of θ.

Doubtless it will not always be profitable to complete the fitting process by computing β and θ_0. The first step would normally be to plot θ against log R, to test whether the data can in fact be fitted by an ordinary logarithmic spiral. If a straight line is not obtained, a plot of θ against (tan $\varphi - \varphi$) will indicate whether the Huxleian growth model is likely to be useful.

Historical Marine Levels in Italy

In 1964, Gunther reported[1] *Lithodomus* borings in the columns of the Temples at Paestum at a maximum elevation of 18·5 m above sea-level. He explained them by a "fall of the land" and by subsequent uplift, and corroborated his hypothesis with numerous observations along the coasts of Italy, Sicily and Malta. His account of the evidence in the *Illustrated London News* of the same year prompted me to visit the site; I later discussed my findings with N. C. Flemming at Cambridge. I have now seen the letters written by Flemming[2] and A. N. Burton[3] to *Nature* in reply to Gunther's communication. Flemming considers that if there has been any earth movement it must have been very localized, which is possible in a seismic coast like that of west Italy; Burton states that, to judge from his own work on raised beaches in Calabria, uplift at the rates implied by Gunther is impossible.

I feel I must enlarge on a point hinted at by Flemming in his phrase "the supposed presence of *Lithodomus* borings in the columns". Gunther himself mentioned that the columns were made of travertine; this is the term generally used in Italy for what (in the present case) should more properly be described as tufa, a porous, spongy limestone deposited by running water on growing plants and thus bearing the imprint of leaves and stems[4]. The columns are thus riddled with holes which need not be attributed to *Lithodomus* and which could provide a determined investigator with evidence of former sea-levels at any height he pleased. The fault lies in the original observations rather than in their interpretation.

CHEMISTRY

Catalysis by Alkali Metal Ions of the Racemization of the *Tris*-oxalato Chromium-III Anion

The rates of racemization of the complexes $M^I_3Cr(oxalate)_3$ have been found to depend on the nature of the alkali metal ion M^I as shown in Table 1.

Table 1

M^I	Li	Na	K	Cs	
$k_1 \times 10^3$ min^{-1}	29·26	30·85	26·91	23 62	all ± 1 per cent

(pH 6·5; temperature 21·6° C; $[M^I_3CrOx_3]$ = 2·3 × 10^{-3} M; no added salt.)

It can be seen that the different cations affect the rate in the order Na > Li > K > Cs—an order of increasing size (if Li^+ is assumed hydrated) and of decreasing co-ordinating power. Beese and Johnson[1] have shown that Li^+ accelerated this racemization more than K^+, but their results were obtained with a large concentration (0·5 M) of added salt (lithium chloride or potassium chloride).

Addition of sodium perchlorate increases the rate of racemization, but at concentrations greater than about 0·1 M added salt the rate of increase in rate against concentration falls off, as shown by the data in Table 2.

Table 2

[sodium perchlorate]	0·0	0·1	0·47	0·98	1·98	4·7	M
$k_1 \times 10^3$ min^{-1}	4 15	4·71	5·59	6·50	7·14	8·13	

(pH = 5·8–6·6*; temperature = 0·1° C; (Na_3 $CrOx_3$) = 0·003 M.)
* The rate of racemization is independent of pH in this region.

This is similar to the acceleration, although much smaller, produced by addition of cupric ions, where it is clear that the initial acceleration is due to co-ordination of one copper ion, and the co-ordination of a second copper ion gives a species which racemizes at a very much slower rate[2]. A similar phenomenon has been observed by Hay and Harvie[3] for the nickel ion catalysed decarboxylation of dihydroxy fumaric acid.

The recent work of Ashley and Hamm[4] on the acceleration of the *trans-cis* isomerization of diaquo *bis* oxalato chromium(III)anion supports the 'one-ended' dissociation hypothesis[5], with the cation co-ordinating to the free end of the half-dissociated oxalate. Such a mechanism probably also operates in the alkali metal catalysed racemization of the *tris* oxalato complex.

Measurement of Graphitic Acid Surface with Polar Molecules

We have been carrying out sorption of polar molecules by graphitic acid, measuring the quantity sorbed in order to determine the interlamellar surface. The following experimental methods were used: (1) volumetric Brunauer–Emmett–Teller (B.E.T.); (2) gravimetric Joly balance[1]; (3) X-ray diffraction. The first two give a measure of the surface, the third technique gives a measure of the increase of space between the layers.

Table 1. SPECIFIC SURFACE OF GRAPHITIC ACID DETERMINED WITH POLAR MOLECULES

Sorbed molecule	Molecule S (Å²)	Technique	Temperature	g/g GA	V_m (cc/g)	Specific surface (m²/g)	d_{GA}	Type of complex
Water	10·8	B.E.T.	20° C		102	298 × 2	9·2	α
Ammonia*	15	B.E.T.	−47° C		147·5	592 × 2	9·2	α
Ammonia*	15	B.E.T.	0° C		154	619 × 2	9·2	α
Ammonia†	15	B.E.T.	0° C		207·4	833 × 2	9·2	α
Acetone	25	B.E.T.	20° C		89·5	550 × 2	9·0	α
Ethylene glycol	33	Joly balance	room temperature	0·2558		1,650	9·06 9·6 (ref 2)	α
n-Butylamine	20 ?	B.E.T.	20° C		136		14·97	β
n-Octanol	20 ?	Joly balance	room temperature	0·791			23 5	β

* Samples oxidized once

† Samples oxidized three times.

S = Surface; V_m = volume of vapour for monolayer; d_{GA} = (001) spacing of graphitic acid in Å.

The following molecules were sorbed: water, ammonia, acetone, ethylene glycol, *n*-butylamine and *n*-octanol.

The experimental results are shown in Table 1. The specific surface of the graphitic acid was calculated according to the formula C_4O_2H of molecular weight 81·05, leading to a value of 1,550 m²/g.

With water, ammonia, acetone and ethylene glycol, the sorbed molecules lie with their axes parallel to the surface of the lamellae giving an α complex[2].

The measurement of the surface in this case presents no difficulty, and with ethylene glycol a value is obtained for the total surface (S_{int} + S_{ext}).

The problem is more complicated if one tries to make a quantitative study of the β-complexes. In these, the molecules are more or less perpendicular to the layer, although some of the terminal carbon atoms may be in contact with the layer[3,4].

The completely erect position of the molecular chain is a limiting case, which is favoured by low temperatures[5].

Thus, the surface covered by butylamine and octanol cannot be calculated until the configuration of these molecules in the sorbed state is known. A calculation of the number of Å² corresponding to each molecule of octanol results in a value of 42 Å² (for specific surface 1,550 m²/g). A calculation of the density of the interlamellar liquid (using the X-ray value of the interlamellar spacing) gives $d_{20°} = 0·54$. The sorbed layer is thus much less dense than the liquid ($d_{20°} = 0·84$).

We intend to make further investigation of the density and heat of sorption of polar molecules with graphitic acid.

Formation of Mercuric Iodo-acetate in Glacial Acetic Acid and its Reactions with Olefines

THERE are many examples in the literature referring to mercury salts of the type $Hg.R_1.R_2$, where R_1 and R_2 are different anions. In aqueous solution it has been shown by Raman spectroscopy that a mixture of mercuric chloride and bromide gives rise to the molecule HgCl.Br (ref. 1), while HgClI exists in the gas phase[2]. Molecular weight and conductance measurements of a mercuric bromide solution of mercuric sulphide indicates, however, that $2HgS.HgBr_2$ is formed[3].

The red polymorphic form of mercuric iodide is sparingly soluble in hot glacial acetic acid but dissolves readily in a solution containing mercuric acetate such that one mole of mercuric acetate just dissolves one mole of mercuric iodide[4]. On cooling the solution yellow needle-like crystals are obtained which, on standing for a few hours, turn red with separation of mercuric acetate. The driving force for solution is the formation of Hg(OAc)I or HgI_2. $Hg(Ac)_2$. To distinguish which of these hetero-anion salts may be formed an ebullioscopic determination of molecular weights was carried out using a conventional all-glass Cotrell pump apparatus. It has been suggested that mercuric acetate in aqueous solution probably consists of indefinitely long chains[5]. Using A.R. glacial acetic acid throughout, recrystallized mercuricac etate and resublimed mercuric iodide, the apparatus was calibrated using triphenyl methane. Over the concentration range 0·025–0·1 M, mercuric acetate was found to be monomeric (found, 335, 330, 324, 312; calculated, 318·7). Recently the molecular weights of mercuric halides in acetone were measured and indicated that they are monomeric in this solution[6]. The observed elevations over a similar concentration range, but containing mercuric iodide, indicated that monomeric Hg(Ac)I was formed (found, 346, 370, 376, 382; calculated, 386·6).

In order to assess the consequences of forming a hetero-anion salt the reaction of mercuric iodo-acetate with olefines was studied. Hugel and Hibou[7] investigated the olefine complexes formed by mercuric acetate and noted that mercuric iodo-acetate does not react directly with 1,2-hexadecene to give $C_{16}H_{32}Hg(Ac)I$. Ethylene was passed into a refluxing solution of mercuric iodo-acetate (3·87 g). After 3 h, mercuric iodide was obtained unchanged from the solution (2·20 g) and the complex $C_2H_4.Hg(OAc)_2$ recovered after evaporation of acetic acid ($C_8H_{10}O_4Hg$ requires C, 14·9 per cent; H, 2·0 per cent—found, C, 14·1 per cent; H, 2·1 per cent). The reaction with 1-dodecene led to quite different products. From a reaction mixture of mercuric iodo-acetate (30·8 g) and 1-dodecene (13·6 g) in refluxing glacial acetic acid mercurous iodide was obtained (9·92 g). On cooling, mercuric iodide (3·36 g) was obtained and, after removal of acetic acid, a heavy unstable oil. Vacuum distillation resulted in the formation of large drops of free mercury; gas chromatographic analysis showed that the distillate consisted of dodecene and two other high boiling products neither of which contained iodine. The resolution of this mixture is the subject of further work.

Photolysis of Organic Sulphides

Irradiation of solutions of diphenylamine with ultraviolet light effects cyclization to carbazole in good yield[1]. It was of interest to determine if diphenyl sulphide would similarly afford 9-thiafluorene, some polymethyl derivatives of which were required. In the event, reaction took a different course, and benzene and diphenyl disulphide were produced. Trace amounts of diphenyl were also detected by gas-liquid chromatography but none of the desired 9-thiafluorene was found. The diphenyl disulphide (m.p. and mixed m.p. 57°–59°) was separated from unchanged sulphide by preparative gas-liquid chromatography; benzene was detected by gas-liquid chromatography but was not isolated. The following mechanism is adequate, assuming initial cleavage into free radicals as postulated in another case[2]. Free radical formation is energetically possible with light of wave-length less than 3900 Å taking the energy of the carbon–sulphur bond to be about 73 kcal/mole (ref. 3).

$$\begin{aligned} \mathrm{PhSPh} &\rightarrow \mathrm{PhSPh}^* \\ \mathrm{PhSPh}^* &\rightleftarrows \mathrm{Ph.} + \mathrm{.SPh} \\ 2\mathrm{PhS.} &\rightleftarrows \mathrm{PhSSPh} \qquad (1) \\ \mathrm{Ph.} + \mathrm{solvent} &\rightarrow \mathrm{C_6H_6} \qquad (2) \end{aligned}$$

Reactions of type (1) and (2) are well known[4]. Lyons has reported[5] that irradiation of diphenyl disulphide in *n*-hexane and other solvents gave thiophenol by dissociation and abstraction of hydrogen from the solvent by thiophenoxyl radicals. No thiophenol could be found among the products obtained in the present experiment using light petroleum (b.p. 40°–60°) as solvent.

A number of other sulphides behaved similarly on irradiation. Thus di-*n*-butyl sulphide was smoothly converted into the disulphide, isolated by preparative gas-liquid chromatography and identified by its infra-red spectrum, and di-*n*-octyl sulphide gave the disulphide and *n*-octane (detected by gas-liquid chromatography). With benzyl phenyl sulphide, which could theoretically cleave in two ways to give either dibenzyl and diphenyl disulphide or benzene and dibenzyl disulphide, only the former reaction occurred, through the most stable pair of radicals. Similarly benzyl *n*-butyl sulphide gave mainly dibenzyl and di-*n*-butyl disulphide. In each case small amounts of phenanthrene and *trans*stilbene were detected by gas-liquid chromatography. Diallyl sulphide was decomposed and sulphur was precipitated, but the only other product was a high boiling liquid shown by gas-liquid chromatography to contain at least four components.

Dibenzyl sulphide predictably gave dibenzyl and dibenzyl disulphide, but an unexpected product was phenanthrene, which was isolated by chromatography on alumina and identified by mixed melting point. The exact sequence of reactions leading to the formation of the phenanthrene is not clear. It seemed likely that it might have been produced by photo-cyclization of stilbene[6], itself formed by dehydrogenation of dibenzyl by benzylthiyl radicals[7]. In agreement a small amount of benzyl mercaptan was detected among the reaction products by gas-liquid chromatography. On the other hand, no more than a trace of 1,8-dimethylphenanthrene was formed when the reaction was carried out in presence of an equimolecular amount of 2,2′-dimethyldibenzyl, suggesting that there may be another route from the sulphide directly to stilbene or phenanthrene. Phenanthrene was also produced, along with some dibenzyl, by irradiation of dibenzyl disulphide, but, surprisingly, the main product of this reaction was dibenzyl sulphide. Prolonged irradiation of either the sulphide or the disulphide resulted in complete destruction of the sulphur compound and formation of a mixture of dibenzyl and phenanthrene in the ratio of approximately 2·5 : 1.

Dissociation of disulphides into radicals on irradiation with ultra-violet light is well known[7,8], but there has apparently been no previous instance of sulphur extrusion from a disulphide by light. The reaction is not general, for both diphenyl disulphide and di-*n*-butyl disulphide were unaffected under the same conditions. Measurements of bond dissociation energies show[3,9] that the carbon–sulphur bond in benzylic sulphides is considerably weaker than that in simple dialkyl sulphides, and it is reasonable to suppose that in dibenzyl disulphide, but not in the other disulphides examined, the usual dissociation into thiyl radicals is accompanied by cleavage of the carbon–sulphur bond, the sulphide then being formed by combination of benzyl and benzylthiyl radicals.

Reactions were conducted for 12–20 h under nitrogen (in the case of diphenyl sulphide oxygen was also used) in a quartz flask with light from a 125 W Mazda mercury vapour lamp from which the outer glass envelope had been removed, using dilute solutions (0·1–0·2 molar) in light petroleum (b.p. 40°–60°). In 'Pyrex', di-*n*-butyl and dibenzyl sulphides were unchanged, but diphenyl sulphide again gave the disulphide.

Complex Formation between Transition Metal Ions and Organic Solvents : Electron Spin Resonance Investigations

The electron spin resonance (ESR) technique provides a powerful tool for investigating transition metal complex formation in non-aqueous solutions. In recent work we have shown[1] that ESR and optical absorption spectra of different paramagnetic ions are changed when glycerol replaces water as a solvent. Both the variation in line width and the optical 'red shift' obtained suggest a change in crystal-field energy levels by spin-orbit mechanisms. Newer theories have linked octahedral–tetrahedral changes to these ligand-field effects on non-bonding *d* electrons[2]. Thus, it might be of interest to investigate the ESR spectra of the chlorides of Mn^{2+}, Fe^{3+} and Cu^{2+} in different organic solvents including dimethylsulphoxide (DMSO), dimethylformamide, formamide, acetone, glycerol and ethanol. These solvents were chosen to provide a varying dielectric constant and base strength since such parameters are known to affect the equilibrium between the octahedral and tetrahedral states.

The ESR spectra were determined with a Varian *V*4500 100-kc ESR spectrometer using a liquid sample accessory. A DPPH standard ($g = 2{\cdot}0036$ as indicated by the arrow in Fig. 1) was used as a reference for marking resonance positions. The first derivative of the absorption curve was recorded. All solvents and hydrated salts used were of reagent-grade quality.

The spectra obtained are shown in Fig. 1. In formamide a Mn^{2+} spectrum (six-line *hf* pattern) similar to that obtained with water can be observed, while all other solvents result in a change of the spectrum. A splitting of the two outer lines and a reduction in intensity is observed with dimethylformamide and DMSO, probably due to the

influence of the two methyl groups present in both solvent molecules. A very broad signal with the normal six-line *hf* pattern superimposed was obtained for Mn–glycerol and Mn–ethanol solutions. Manganese chloride is very slightly soluble in acetone (yellowish-brown); therefore, the ESR spectrum of a saturated solution was recorded. All other solutions were colourless except for water and glycerol, which were pink.

Considerable changes in Cu^{2+} *hf* pattern were found with different solvents. In contrast to Mn^{2+}, Cu^{2+} in formamide gave a very unusual *hf* pattern. Copper chloride was found to be quite soluble in all solvents giving a blue colour in formamide and water, yellowish-green in DMSO and dimethylformamide, slightly green in glycerol, green in ethanol, and amber in acetone.

The Fe^{3+} spectra for water and ethanol are very broad, which, in the case of water, is probably due to the hydration effect. The high dielectric constant of water and its base strength are responsible for a complete dissociation of the tetrahedral form. While all the spectra obtained were near the free-electron value, as expected for *S*-state ions, the Fe^{3+}-glycerol signal is at a considerably higher *g*-value[1]. No signal could be obtained with formamide as a solvent, a result also observed by Swanson *et al.*[3], who assumed a breakdown of the tetrachloroferrate complex, $(FeCl_4)^-$, in solvents of high dielectric constant. The tetrahedral complex of iron has been investigated spectrophotometrically by Katzin[4] and was attributed recently by Swanson *et al.*[3] as being responsible for the ESR signal obtained. Since only halide anions seem to form the tetrahedral complex, an iron salt of other anions should not give a signal. Ferric nitrate or ferric sulphate, dissolved in DMSO, confirmed this prediction. Addition of small amounts of magnesium chloride or hydrochloric acid to this solution, however, resulted in a strong iron signal similar to the one obtained with ferric chloride–DMSO solutions. Addition of other halide anions (Br^-, I^-, F^-) in the form of their potassium salts to the ferric nitrate–DMSO solution did not produce an iron ESR signal. Nevertheless, distinct colour changes in the solutions on the addition of these anions suggest alterations in the electronic energy-levels of the ferric ion. Optical absorption studies are at present being undertaken to obtain more information. All Fe^{3+} solutions were yellowish with the exception of formamide which gave a brown colour.

BIOCHEMISTRY

Kinetics of Ribonucleic Acid Synthesis on Deoxyribonucleic Acid Template

The purpose of this communication is to propose a mechanism, and to establish on its basis a system of equations, for the description of the kinetics of the synthesis of ribonucleic acid (RNA) templated by deoxyribonucleic acid (DNA). The models proposed[1] for the kinetics of the DNA synthesis cannot be extended to the RNA synthesis, since they assume that the uncoiling of the DNA double helix is the rate determining step. The time required for the unwinding of a DNA molecule with a length of 10^4 nucleotide pairs is of the order of about 30 sec (ref. 1). The *in vivo* synthesis rate for RNA is experimentally found to be much larger. It is therefore reasonable to assume that, in contrast to the replication of the DNA molecule, the RNA synthesis does not require the unwinding of the whole DNA double helix but only of a short part of it.

The essential characteristics of the RNA synthesis process seem to be (for a detailed discussion see ref. 2): (i) the formation of an unwound zone at the beginning of the DNA double helix; (ii) the binding of RNA polymerase (*E*) at the beginning of the DNA molecule; (iii) the step-by-step advancement of RNA polymerase as the unwound zone advances on the DNA molecule; (iv) the step-by-step synthesis of the RNA chain as RNA polymerase advances; (v) the step-by-step detachment of the RNA from the DNA as the uncoiled zone advances and the region behind it is rewound.

The mechanism proposed here is described in more detail by the following chemical reactions:

$$\mathrm{DNA} + E \rightarrow \mathrm{DNA}\cdot E \qquad (0)$$

$$\mathrm{DNA}\cdot E + X_1\mathrm{TP} \rightleftarrows \mathrm{DNA}\cdot E\cdot X_1 \qquad (1a)$$

$$\mathrm{DNA}\cdot E + Y_{1K}\mathrm{TP} \rightleftarrows \mathrm{DNA}\cdot E\cdot Y_{1K} \qquad (1b)$$

$$\mathrm{DNA}\cdot E\cdot X_1 \rightarrow \mathrm{DNA}\cdot X_1\cdot E \qquad (1c)$$

$$\vdots$$

$$\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}E + X_i\mathrm{TP} \rightleftarrows \mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot X_i \qquad (2a)$$

$$\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E + Y_{iK}\mathrm{TP} \rightleftarrows \mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot Y_{iK} \qquad (2b)$$

$$\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot X_i \rightarrow \mathrm{DNA}\cdot X_1X_2\cdots X_i\cdot E \qquad (2c)$$

$$\vdots$$

$$\mathrm{DNA}\cdot X_1X_2\cdots X_n\cdot E \rightarrow \mathrm{DNA} + X_1X_2\cdots X_n + E \qquad (3)$$

In the growth reactions (2*a*, 2*b*) of the RNA strand it is assumed that the three non-complementary (false) ribonucleoside triphosphates (Y_KTP) compete with the complementary one (XTP) for that position on the DNA matrix which the latter ought to occupy, but that they are not included in the growing RNA chain. This assumption is based on a similar competitive inhibition (called 'low efficiency inhibition') observed in the synthesis of polyadelinic acid on single-stranded DNA in the presence of large concentrations ($> 10^{-4}$ mol/l.) of a nonadenilic YTP[2].

If a steady state and an excess of RNA polymerase are assumed, the foregoing reactions can be described by the following equations:

$$\vdots$$

$$\frac{dA_i^*}{dt} = \zeta c A_{i-1}^+ - (\zeta' + \nu) A_i^* = 0 \qquad (4)$$

$$\frac{dA_{iK}^0}{dt} = \eta c A_{i-1}^+ - \eta' A_{iK}^0 = 0 \qquad (5)$$

$$\frac{dA_i^+}{dt} = \nu A_i^* - (\zeta + 3\eta) c A_i^+ + \zeta' A_{i+1}^* + \sum_{K=1}^{3} \eta' A_{i+1,K}^0 = 0 \qquad (6)$$

$$\vdots$$

$$\frac{dA_n^+}{dt} = \nu A_n^* - \lambda A_n^+ = 0 \qquad (7)$$

$$\varphi = n\lambda A_n^+ \qquad (8)$$

$$N = \sum_{i=1}^{n} (A_i^+ + A_i^* + \sum_{K=1}^{3} A_{iK}^0) \qquad (9)$$

In these equations c is the concentration of the four ribonucleoside triphosphates (which are considered equal), A_i^+ the concentrations of the $\mathrm{DNA}\cdot X_1X_2\cdots X_i\cdot E$ complexes, A_i^* that of the $\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot X_i$ complexes, A_{iK}^0 that of the $\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot Y_{iK}$ complexes, n the length (nucleotide number, $n \approx 10^4$) of the synthesizing DNA strand, φ the RNA synthesis rate, N the number of DNA molecules with RNA polymerase, and ζ, ζ', ν, η, η' and λ the rate constants for the different reactions.

For the RNA synthesis rate Φ, expressed as the number of nucleotides polymerized per second and per molecule of DNA with RNA polymerase, one obtains:

$$\Phi \equiv \frac{\varphi}{N} = \frac{\zeta\nu c}{(\zeta'+\nu)\left\{1 - \frac{1}{n} + \left[\left(1 + \frac{\nu}{n\lambda}\right)\frac{\zeta}{\zeta'+\nu} + 3\frac{\eta}{\eta'}\right]c\right\}} \qquad (10)$$

If it is assumed that: (i) the step-by-step advancement of the RNA polymerase, the uncoiling of the DNA, and the inclusion of the ribonucleotide (X_i) in the growing RNA chain processes (2*c*) are fast in comparison with those (2*a*) of the formation and dissociation of the $\mathrm{DNA}\cdot X_1X_2\cdots X_{i-1}\cdot E\cdot X_i$ complexes (that is, $\nu \gg \zeta\eta'/3\eta$ and $\nu \gg \zeta'$), and (ii) the time needed for the release of the synthesized RNA molecule and the RNA polymerase is small in comparison with the time needed for the RNA synthesis (that is, $1/\lambda \ll n/\nu$), equation (10) becomes:

$$\frac{\varphi}{N} = \frac{\zeta c}{1 + 3\frac{\eta}{\eta'}c} \qquad (11)$$

The rate constant ζ is probably determined by collisions of the XTP molecules from the solution with the deoxynucleotide which has reached the RNA polymerase, and it would thus be[4,5] about 6×10^8 l.mol^{-1}s^{-1}.

We evaluate η/η' using the experimental results for the 'low efficiency' inhibition of the polyadenilic acid synthesis by competition with a nonadelinic YTP; the synthesis rate is reduced to half the value valid for 'high efficiency' inhibition (that is, for very small $10^{-6} - 10^{-7}$ mol/l. YTP concentrations), at concentrations of about 5×10^{-4} mol/l. for the non-adelinic YTP[3]. If this synthesis is considered to be similar to that of the RNA, and only with a different 'slippage' rate constant (instead of the ν constant for the processes (2*c*)), a value $\eta/\eta' \approx 2 \times 10^3$ l.$^{-1}$ mol is obtained.

With $\zeta = 6 \times 10^8$ l.mol^{-1}s^{-1} and $\eta/\eta' = 2 \times 10^3$ l.mol^{-1}, equation (11) shows that φ/N tends to $1{\cdot}0 \times 10^5$ for sufficiently high value of c and that half this rate is attained for $c \approx 1{\cdot}7 \times 10^{-4}$ l.$^{-1}$ mol.

The rate of the ribosomal RNA synthesis in *Escherichia coli* (where it represents about 90 per cent of the total RNA) is about 10^5 nucleotides polymerized per second[5] by the, at most, 10 DNA molecules which synthesize it[6,7]; this would correspond to $\varphi/N \approx 10^4 \ldots 10^5$.

We notice that for *in vitro* synthesis of RNA the reaction rate is much smaller than that predicted by equation (11), but that half of the high concentration rate is attained also for $c \approx 1{\cdot}3 \times 10^{-4}$ l.$^{-1}$ mol (ref. 8). The small *in vitro* rates are probably due to the fact that only a few of the DNA molecules have RNA polymerase; these rates increase proportionally with the amount of the enzyme added[9].

Lipid Metabolism in Hypervitaminosis A

Since the report of Moore and Wang[1] on hypervitaminosis A in rats, it is now recognized that administration of excessive doses of vitamin A influences the general metabolism of the host. Ray and Sadhu[2] reported that administration of large doses of vitamin A to rats caused an increase in liver fat. March and Biely[3], and Wood[4] reported that administration of vitamin A to young chickens lowered the elevated plasma cholesterol which resulted from the inclusion of 1 per cent cholesterol in their diet. Kinley and Krause[5] also reported the hypocholesteraemic action of vitamin A in atherosclerotic patients. Pallotatta and Krause[6] reported that administration of vitamin A elevated serum phospholipids. Van Bruggen and Straumfjord[7], on the other hand, observed that long-term administration of large doses of vitamin A to patients

raised their plasma cholesterol and phospholipid levels. Misra[9] observed that administration of excessive doses of vitamin A to rats lowered their plasma cholesterol and raised phospholipid-levels. This communication describes the results obtained on the tissue lipids of rats given excessive doses of vitamin A.

Male Wistar albino rats weighing 145–150 g were divided into two groups of six each and were kept on stock diet and water *ad libitum*. To one group 10^5 I.U. of retinol (Prepalin, Glaxo Ltd., India) were given intramuscularly daily for ten days. Rats without retinol were the control. A daily record of their food consumption and a weekly record of their body-weight were maintained. On the tenth day rats in both groups were intraperitoneally given a saline solution of $NaH_2{}^{32}PO_4$ (100 μc./100 g body-weight). After 6 h, rats were killed by decapitation, and liver, kidney, small intestine (about 30 cm), brain and heart tissues were quickly removed, cleaned, weighed and transferred to a volume of chloroform : methanol (2 : 1, v/v) for lipid extraction. Intestine was rinsed thrice with ice-cold saline before lipid extraction. Blood was drawn before killing the animals for vitamin A assay in plasma by the method of Bessey *et al.*[9]. Lipids from the tissues were extracted according to the method of Folch *et al.*[10], and dissolved in 5 ml. chloroform. Weights of the tissue lipids were determined by weighing an aliquot to a constant weight. Lipid extracts of the tissues were analysed for cholesterol[11] and phosphorus[12]. ^{32}P activity of lipid solutions was determined in a window-less gasflow counter.

No difference was observed in the daily food consumption and body-weights of the rats in both groups at the time of death. Vitamin A values in plasma were: control, 60–80 I.U.; experimental, 600–800 I.U. per 100 ml. plasma. Rats given excessive doses of vitamin A showed rawness of the skin, epilation, bleeding around the nose and bent and limping posture Effect of hypervitaminosis A on tissue lipids of rats is shown in Table 1. Total lipids of liver, intestine, and brain showed a significant increase and kidney lipids a marked decrease in rats given excessive doses of vitamin A than the control group. Administration of large doses of vitamin A also caused significant elevations in the cholesterol levels of liver, kidney, intestine, and brain tissues as compared with the control group. Hypervitaminosis A did not affect phospholipid phosphorus levels and their specific activities of the above tissues except kidney where a marked increase in its phospholipid specific activity is noted (Table 1). Heart tissue lipids, cholesterol, and phospholipid phosphorus were not significantly affected in hypervitaminosis A.

The values are mean ± standard error of six animals.
P values < 0 05 are significant.

Reported results are in agreement with those observed by Ray and Sadhu[2]. It is difficult to arrive at any conclusion regarding the mechanism by which administration of excessive doses of vitamin A brings about the observations made on rat tissue lipids. It is also not certain whether vitamin A influences the lipid metabolism directly, or these changes result due to an indirect and unspecific reaction of vitamin A or a substance or substances derived from it.

I thank Mr. N. Srivastava for technical assistance.

Ethionine-induced Hypoglycaemia

Although considerable attention has been directed to the role of impaired release of liver triglyceride into plasma in the development of the fatty liver induced in rats by ethionine[1,2], it seems unlikely that such a mechanism, by itself, adequately accounts for the fatty liver. Lombardi and Recknagel[1] have presented evidence showing that ethionine impaired hepatic triglyceride release in both male and female rats; however, it is well known that the male is surprisingly resistant to the development of a fatty liver[3]. Observations that glucose administration either prevents[3,4] or decreases[5,6] hepatic triglyceride accumulation directed attention to the possibility that hypoglycaemia occurs after an injection of ethionine, thus serving as a stimulus for fat accumulation in the liver.

Single injections of *d,l*-ethionine dissolved in isotonic saline (25 mg/ml.) were given intraperitoneally in a final dose of 75 mg/100 g body-weight to female and male Sprague–Dawley rats weighing 180–230 g. Methionine in equimolar doses, either alone or mixed with ethionine, was also administered in single injections to some animals. Control rats received comparable volumes of saline. Neutralized aqueous solutions of adenosine triphosphate (Sigma Chemical Co.), with concentrations of 100 mg/ml., were given subcutaneously in 100 mg doses at 0, 2 and 6 h. Food was denied to groups of animals (designated 'fasted') 12–15 h prior to injection and thereafter; however, water was allowed *ad libitum*. Further groups of animals (designated 'fed') were permitted access both to food and water prior to, and after, ethionine administration. The rats were anaesthetized with ether at varying intervals, bled from the aorta, and blood sugar determined in triplicate by the method of Somogyi[7]. The results are given in Table 1.

Blood glucose concentration fell 4 h after administration of ethionine in female rats fed up to the time of injection, and allowed access to food thereafter. Decreased blood sugar concentrations persisted for at least 48 h. A more marked lowering of blood sugar was observed in female rats fasted before and after the injection of ethionine. A distinct difference in susceptibility to hypoglycaemia was observed in male rats. Blood sugar did not fall in 'fed' males, and the decrease noted in 'fasted' males occurred relatively late, and was much smaller than in females.

Methionine and ATP prevented hypoglycaemia in 'fed' females. ATP lessened the fall in blood sugar induced by ethionine in 'fasted' females 4 h after injection, and at 8 h blood glucose-levels had returned to the values found in saline controls.

The mechanism of hypoglycaemia has not been elucidated by the present studies and this is at present being investigated. The observation that blood sugar fell 4 h

* Numbers in parentheses indicate number of animals in each group. Blood glucose values represent the mean for the animals in each group.

after ethionine in female rats previously fed up to the time of injection suggests that interference with gluconeogenesis was not the major factor, at least not in the early stages. Since (1) ATP levels in liver[8], and possibly in other tissues as well, decrease markedly after ethionine injection, and (2) the fall in blood sugar was modified in 'fasted' animals by administration of ATP, it is tempting to speculate that ethionine led to a significant increase in glucose utilization. Activation of phosphofructokinase by a fall in ATP might be expected to stimulate glycolysis[9]. If of sufficient magnitude, such an alteration could account for significant hypoglycaemia, and account for the decrease in liver glycogen previously noted after ethionine[10]. It is not known at present whether the differing propensities for male and female rats to develop hypoglycaemia is related to differing degrees of ATP depletion, as few measurements have been reported of ATP-levels for male rats. In one communication in which such data are presented[8], hepatic levels of ATP had fallen less drastically in males than in females at 5 h after administration of ethionine.

Regardless of the mechanism by which hypoglycaemia is produced, the present data also provide evidence that hypoglycaemia may play an important part in the genesis of fatty liver induced by ethionine. In recent years, considerable emphasis has been directed to the phenomenon of impaired triglyceride removal from liver as the major factor accounting for triglyceride accumulation after ethionine administration[1,2]. Relatively little attention has been directed to the possibility of increased fat delivery to the liver although it has been demonstrated that the increased fatty acids found in liver triglyceride are most probably derived from adipose tissue[11,12].

Profound hypoglycaemia, as noted in the fasted females, might be expected to stimulate release of non-esterified fatty acids from adipose tissue, and, indeed, increased levels of these have been observed in the blood of rats receiving ethionine[13,14]. Augmented delivery of non-esterified fatty acids to the liver with subsequent incorporation into triglyceride may be important before increased hepatic triglyceride levels become manifest. Thus, glucose administration, which is known to prevent[3,4] or decrease[5,6] hepatic triglyceride accumulation, may do so indirectly by alleviating hypoglycaemia. The well-known difference in susceptibility of female and male rats to development of fatty liver, not adequately accounted for by impaired hepatic triglyceride release, may also be explained by the differing propensities for developing hypoglycaemia. Thus, increased resistance to ethionine-induced fatty liver in males[15] may be related to their resistance in developing a fall in blood sugar. Finally, although ATP administration has been shown to augment hepatic ATP levels and to prevent the development of fatty liver[16,17]—presumably by correcting the ethionine-induced impairment in hepatic lipoprotein synthesis—this need not be the only mechanism. As shown by the present investigations, interference with the development of profound hypoglycaemia by ATP may also play an important protective part.

These speculations do not detract from the probable importance of impaired lipoprotein synthesis as a contributing factor in the genesis of ethionine fatty liver. Rather, they also direct attention to additional important factors, presumably including increased fat mobilization to the liver, in this form of acute experimentally induced fatty liver. Furthermore, the present data indicate that hypoglycaemia is probably the important stimulus for such augmented fat accumulation in the liver.

These investigations were supported by research grants *HE*-03439 and *NB*-05841 from the U.S. Public Health Service.

α-Hydroxybutyric Dehydrogenase Activity of Human Vascular Tissue

In recent years, several investigations have been reported on the α-hydroxybutyric dehydrogenase (HBD) activity in human serum and in various animal organs[1–5]. This enzyme catalyses the reversible reaction:

α-hydroxybutyric acid + DPN ⇄ α-ketobutyric acid + DPNH

Reliable measurement of the enzyme activity is possible by determining the rate of reduction of α-ketobutyric acid with reduced diphosphopyridine nucleotide (DPNH). No research has previously been conducted on the HBD activity exhibited by vascular tissue. The present investigation was designed to determine the activity of this enzyme in various types of human blood vessels. To evaluate the association between arteriosclerosis and HBD values, enzymatic measurements were made separately on normal and lipid-arteriosclerotic portions of tissue.

The vascular samples were obtained fresh at autopsy at the St. Louis City Morgue from individuals ranging in age from 3 months to 85 years. After rinsing the specimens with isotonic saline solution, the adventitia was removed and 5 per cent aqueous homogenates of intima-media layers were prepared at 4° C with a tissue grinder (Kontes-Duall type). The homogenates were afterwards centrifuged at 25,000 r.p.m. and 0·05 ml. portions of the supernatants immediately used for measurement of enzyme activity. The HBD determinations were performed as described by the Sigma Chemical Co.[6]—a method similar to that used by Elliott and Wilkinson[2] for the assay of rabbit liver, heart and kidney tissue. The tests were conducted at 25° C.

The 0·05 ml. 5 per cent homogenate supernatant was first incubated with DPNH in 2·8 ml. phosphate buffer, *p*H 7·4, for 30 min; after this pre-incubation period, unspecific oxidation of DPNH was no longer detectable. 0·1 ml. of α-ketobutyrate solution was then added to the sample and, after thorough mixing, the rate of DPNH oxidation was determined at 340 mμ in a Beckman *DU* spectrophotometer provided with thermospacer equipment. The millimolar concentrations in the final reaction mixture were: α-ketobutyric acid, 4·25; DPNH, 0·1; phosphate buffer, 95·0. The optical density readings were made at 1-min intervals against a reference cuvette containing a dichromate solution of appropriate concentration. Linearity was observed between time of reaction and rate of DPNH oxidation during periods of 8–10 min; under the conditions used, the activity recorded was proportional to enzyme concentration. A blank in which the homogenate supernatant was replaced with water was run with each set of analyses. The observed HBD values are expressed as millimoles of substrate metabolized/g wet tissue/h. In addition, activities calculated on the basis of fresh tissue nitrogen content are reported.

Table 1. α-HYDROXYBUTYRIC DEHYDROGENASE ACTIVITIES OF HUMAN VASCULAR TISSUE

	No. of samples	mmoles of substrate metabolized/g wet tissue/h		mmoles of substrate metabolized/g tissue nitrogen/h	
		Mean	*S.D.*	Mean	*S.D.*
Thoracic descending aorta:					
Normal	54	0 329	0·131	8·51	3 37
Lipid-arteriosclerotic	31	0·252	0 098	7·53	2·62
Pulmonary artery	25	0·398	0·124	11 78	3 68
Coronary artery:					
Normal	15	0 458	0 196	13·96	5 92
Lipid-arteriosclerotic	5	0·200	0 099	6·48	2·82
Vena cava inferior	6	0·530	0·112	15·00	3 25

The mean HBD activities of vascular samples are listed in Table 1. Distinctly higher values were observed for the pulmonary artery, coronary artery, and inferior vena cava than for the aorta. Moderately lower enzymatic activities were displayed by arteriosclerotic than by normal tissue portions of the same aortic specimens (wet tissue = 81 per cent, t of difference = 3·95; tissue nitrogen = 89 per cent, t of difference = 1·85). A decrease in HBD activity with age was noted for both normal ($r = -0·27$, $t = 2·02$) and arteriosclerotic ($r = -0·56$, $t = 3·58$) aortic tissue.

Although the HBD activity observed for human aortic tissue is less than 0·5 per cent of that reported by Konttinen and Halonen[4] for liver tissue, a comparison of this dehydrogenase with other enzymes recorded for human arterial tissue[7] shows that α-hydroxybutyric dehydrogenase belongs to the group with highest vascular activities. This suggests that HBD may play a significant part in the intermediary metabolism of the vessel wall.

Kynurenine in Rat Hair

THE pelage of certain murine rodents contains substantial amounts of fluorescent tryptophan metabolites[1]. In the laboratory rat *l*-kynurenine[2] is the principal compound present, with relatively small amounts of kynurenic acid, *N*α-acetyl-*l*-kynurenine and other fluorescent compounds. It is interesting to know what drain this constitutes on the total tryptophan pool in the rat[3,4]; and since tryptophan has been suggested as a possible precursor of red hair pigment, phenomelanin[5], how the amounts of kynurenine compare in the hair of rats with different coat colours.

H. Takahashi has determined the amount of kynurenine in the hair of albino rats and some strains of mice after strong hydrolysis in hydrochloric acid[6]. The method used was the ion-exchange chromatographic assay published by Brown and Price[7]. No appreciable amount of kynurenine was found in the hair investigated except albino rat hair. Albino rat hair, washed with very dilute detergent, gave an average value of 2 mg of kynurenine per 100 mg of dry hair weight. There is about 2 g of hair on a 125 g rat. This means that approximately 40 mg of kynurenine is 'excreted' with the growing hair during replacement of the post-natal pelage in rats between 4 and 7 weeks old, and corresponding amounts during subsequent periods of anagen in their hair cycle of the adult rat[8].

I have obtained slightly lower values by the method of Spăček[9], described here, and also found that the amount of kynurenine plus acetyl kynurenine (and kynurenic acid by chromatography[1]) is independent of coat colour, the content in the pelage being approximately the same in albino, black (melanin), and cinnamon (phenomelanin) rats. In the cinnamon rat there is consequently no evidence of a grossly altered kynurenine content in the hair due to production of phenomelanin. The possibility that kynurenine is taken up into rat hair directly from the circulating pool must be entertained, since this is true of iodide[10] and 9-phenyl-5 : 6-benzo-iso-alloxazine[11]. In the black rat fluorescence of the pelage is largely quenched by melanin *in situ*.

1 g of hair, weighed in room air, was placed in a 500-ml. boiling flask with 100-ml. distilled water, boiling granules and silicone antifoaming agent. The flask was placed on a pre-heated electric heater and 15 g sodium hydroxide added. The powerstat was adjusted to deliver the first 50 ml. of distillate in 20 min into a fractionating well immersed in an ice bath. After 50 ml. had collected, the condenser was washed with 10 ml. of water and this was added to the distillate. The distillate was transferred to a pre-cooled separatory funnel. The fractionating well was rinsed with 10 ml. of water and this was added to the contents of the separatory funnel. The separatory funnel and contents were cooled to 5° C and 50 ml. of cold diethyl ether was added and shaken. After 1 h separation at 5° C the ether layer was collected into a stoppered flask. The water layer was returned to the funnel and re-

Table 2. Values obtained from Guinea-pig, Mouse and Human Hair (μg kynurenine per g of hair)

Guinea-pig (red)	25 μg/g*
(white)	4 μg/g
(black)	7 μg/g
Mouse (albino)	7 μg/g
Human (red)	27 μg/g*

* The slightly higher values obtained from red hair may have significance with respect to the synthesis of pheomelanin (ref. 5). This could also result from the presence of tryptophan *per se* with the method of determination used (ref. 14).

extracted with 25 ml. of cold ether. The water layer was discarded and the combined ether layers made up to 75 ml. and returned to the flash. Absorption at 360 mμ was determined in a Beckman *DU* spectrophotometer, the ether extract being kept in an ice bath during the procedure.

Clean, clipped rat hair was used in the investigation. A portion of this hair was washed through six 15-min changes of distilled water with constant stirring, drained dry in a Büchner funnel between changes, followed by a 15-min extraction with diethyl ether, after which the hair was thoroughly air dried. This is referred to as 'washed hair' in this communication. Healthy albino rats of the Holtzman strain and laboratory rats with cinnamon, black and cream dilute coat colour[12] were used in the investigation. The results of the assays are shown in Table 1. The same procedure was applied to samples of red human hair, guinea-pig hair and albino mouse hair, without obtaining significant values to indicate the presence of kynurenine in the hair (Table 2). A single determination of the amount of kynurenine lost in one 15-min washing with water accounted for 1·2 mg of a 1·7 mg difference between washed and unwashed hair. Paper chromatography of the fluorescent ether fraction with Mason and Berg's solvent system[13] revealed a single blue-white fluorescent spot, R_F 0·9 ±, which developed a salmon colour with Ehrlich's reagent. Determination of the ultra-violet absorption spectra of the presumptive

Inhibition of Choline Acetyltransferase by Excess Cysteine

The first demonstrations of an enzyme that would synthesize acetylcholine (ACh)—originally designated choline acetylase but now called choline acetyltransferase (acetyl-CoA: choline-O-acetyltransferase, *EC* 2.3.1.6.)—depended on the presence in the tissues of other endogenous enzymes which would synthesize acetyl-CoA. Even when the substrate role of acetyl-CoA had been appreciated, however, it was found that in order to realize the maximal activity of the enzyme, provision had to be made to couple it with another enzyme system which would produce acetyl-CoA continuously from suitable precursors. Compared with the production from such coupled systems the amount of ACh produced from added synthetic acetyl-CoA was as little as 20 per cent in the experiments of Reisberg[1] and about 50 per cent in those of Smallman[2] and of Morris and Tuček[3]. However, McCaman and Hunt[4] have obtained proportionately much higher yields of ACh in a buffer-substrate system containing synthetic acetyl-CoA, choline, eserine, magnesium sulphate, bovine plasma albumin and a high concentration of sodium chloride. Their incubations were conducted at *p*H 7·4. These authors considered that their higher yields of ACh depended on the replacement of potassium with a high concentration of sodium ions, but it appears that other factors may be more important.

We have now been able to demonstrate that rates of ACh synthesis either equal to, or greater than, those found by McCaman and Hunt[4] can be obtained from rabbit brain extracts when cysteine is omitted from the incubation medium. Our experiments have been performed on crude extracts of acetone-dried rabbit brain, on crude sucrose homogenates of the electric organ of *Torpedo marmorata* (see Morris, Bull and Hebb[5]) and on preparations of these enzymes partially purified by ammonium sulphate fractionation. The inhibitory effect of cysteine on the *Torpedo* enzyme when incubated with synthetic acetyl-CoA is shown in Fig. 1. In this experiment the incubation *p*H was 6·9, a value near the optimum for a

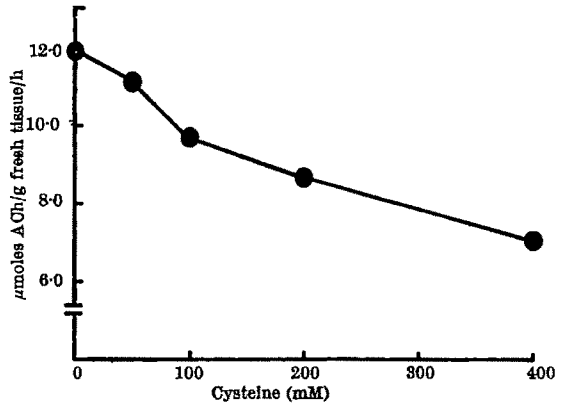

Fig. 1. Effect of cysteine on ACh synthesis by extracts of the electric organ of *Torpedo*. Incubation medium contained (μmoles/ml.): potassium chloride, 200; phosphate-citrate buffer, *p*H 6·9, 40; choline chloride, 24; eserine sulphate, 0·26; acetyl-CoA, 0·35; 20 μl. of partially purified *Torpedo* extract equivalent to 30 mg electric organ and various concentrations of cysteine. Temperature, 39°; *p*H 6·9; incubation time, 10 min. The yield of ACh from the coupled enzyme system at this *p*H and temperature was 14·6 μmoles ACh/g fresh tissue/h

coupled enzyme system containing phosphotransacetylase (acetyl-CoA : orthophosphate acetyltransferase, *EC* 2.3.1.8), acetylphosphate and CoA for the enzymatic production of acetyl-CoA. However, it appears that the *p*H optimum of choline acetyltransferase itself is nearer to 7·5, and at this *p*H the influence of cysteine on the yield of ACh from synthetic acetyl-CoA is correspondingly greater. The rate of synthesis of ACh from partially purified extracts of rabbit brain with synthetic acetyl-CoA at *p*H 7·5 in the absence of cysteine is greater than that obtained with the coupled system under optimal conditions (see Table 1). Cysteine is required in the coupled system for maximum activity.

Table 1. Effect of Cysteine, Sodium and Potassium on Acetylcholine Synthesis by Rabbit Brain Choline Acetyltransferase at *p*H 7·5

Enzyme	Incubation type	Cysteine (mM)	Sodium (mM)	Potassium (mM)	μMoles ACh per g fresh tissue per h
Crude	Acetyl-CoA	0	0	300	4·61
	Acetyl-CoA	0	300	0	5·41
	Coupled system	23	60	180	5·41
Partially purified	Acetyl-CoA	23	0	300	3·49
	Acetyl-CoA	0	0	300	8·61
	Acetyl-CoA	23	300	0	2·61
	Acetyl-CoA	0	300	0	6·30
	Coupled system	23	60	180	5·32

In both systems it is necessary to add monovalent cations, potassium or sodium, to obtain maximal yields of ACh. In some circumstances, we have found that potassium is better than sodium, but this is not invariably so. Sometimes sodium gives higher yields and this seems to depend on whether the enzyme is in the crude state and from what tissue it is obtained. It will be seen from Table 1 that 300 mM sodium supports a higher rate of ACh synthesis by crude rabbit brain than does an equivalent concentration of potassium, a result in qualitative agreement with McCaman and Hunt[4]. With partially purified enzymes, however, potassium is better than sodium.

In the experiments described here, the enzyme preparations were dialysed against 0·05 M-*tris*-thioglycollate buffer, *p*H 6·6, to reduce the endogenous sodium and potassium to a minimum. Subsequent measurements of these ions revealed that all but a trace had been removed. Enzymes containing no thioglycollate give much lower yields of ACh and crude rabbit brain extracts have the same specific activity (3·67 μmoles ACh/g fresh tissue/h) as reported by McCaman and Hunt[4]. It is thought that the low concentration (1 μmole/ml.) of thioglycollate present in most of our experiments may be necessary for the stability of the enzyme. In this connexion it is of interest that we have so far been unable to obtain identical rates of synthesis of ACh with the synthetic acetyl-CoA and coupled enzyme systems using partially purified placental choline acetyltransferase. The latter is considerably less stable than the enzyme from rabbit brain.

From experiments designed to determine the concentration of acetyl-CoA required to saturate our choline acetyltransferase preparations it is possible to obtain approximate K_m values for acetyl-CoA. At 39° C the K_m is $1{\cdot}67 \times 10^{-4}$ M for *Torpedo* and $4{\cdot}9 \times 10^{-5}$ M for rabbit brain enzyme. At this temperature the yield of ACh from *Torpedo* choline acetyltransferase with synthetic acetyl-CoA is 80–90 per cent of that obtained from the coupled enzyme system, but at 25° C, a temperature much closer to that which the enzyme in this species is normally exposed, the yields of ACh from the two incubation systems are equal.

Brain Myelination after Neonatal Administration of Oestradiol

Oestradiol administered neonatally hastens functional brain maturation of the young rat as demonstrated by electroshock techniques[1]. The mechanism of this action is unknown, but it has been suggested that it is related to changes in brain metabolism and/or myelination[1]. Postnatal histological studies of the brain of the normal rat indicate that the rate of myelination in the hypothalamus is greatest between 10 and 20 days of age[2,3]. In the cortex this process begins on about day 12 and continues until about day 60 of age[4]. The present investigation was undertaken to learn whether or not early postnatal injection of oestradiol influences the rate of brain myelination in the developing rat, and whether it thereby hastens functional brain maturation.

Ten litters of six female rats each were kept with lactating mothers until they were killed at either 15 or 20 days of age. Food (a standard rat diet in pellets) and water were given *ad libitum* to the mothers throughout the experiment. The infants in each litter were divided equally into controls and rats to be injected with oestradiol. Oestradiol suspended in 'Mazola' oil was injected subcutaneously in a daily dose of 100 μg/100 g body-weight for 4 consecutive days beginning when the animals are 6 days old. Controls were injected with 'Mazola' oil alone. Half the animals were killed by decapitation on day 15 and the other half on day 20. These ages were selected because they correspond with critical changes in electroshock seizure responses[1].

After fixation in 10 per cent formalin for one week, the hypothalamus and sensory-motor cortex of each brain were separated, dehydrated, embedded in paraffin, sectioned at 6μ and stained with the modified Mann stain[5]. Fibres were selected at random and the smallest cross-sectional diameter of the myelin sheath and of the axis cylinder was measured with an ocular micrometer at a magnification of 1,000. The cross-sectional area of the myelin sheath was calculated by subtracting the area of the axis cylinder from the total fibre area. Ten measurements were taken for each animal. The significance of differences between groups was calculated by the *t*-test. The results obtained are summarized in Table 1.

In the hypothalamus of the controls, the cross-sectional area of myelin increased significantly between 15 and 20

Table 1. Mean Cross-sectional Areas of Myelin Sheaths in the Hypothalamus and Sensory-motor Cortex of Control and Oestradiol-treated Rats

* Mean ± *S.E.*

† Values based on *t*-test for significance of difference of means (controls versus oestradiol).

‡ Values based on *t*-test for significance of difference of means (15 versus 20 days).

days of age. In rats treated with oestradiol, myelin at 15 days of age was significantly greater than in the controls. Since myelin in the hypothalamus of treated rats does not significantly increase between 15 and 20 days of age, it would appear that in these rats, but not in the controls, the period of rapid myelination in the hypothalamus is almost complete at fifteen days. Thus the period of rapid myelination in the hypothalamus was accelerated by oestradiol.

In contrast to the hypothalamus, the sensory-motor cortex of control rats did not show a significant increase in myelin between 15 and 20 days of age. This is in agreement with other investigations[4] which report that myelination in these areas of the brain occurs slowly, over a relatively long period of time, and is complete at about 60 days of age. Similarly, the cortices of treated rats showed no increase in myelin between 15 and 20 days. At both ages, however, myelination was more complete after oestradiol.

The precocious laying down of the myelin sheath around nerve fibres in the rat brain, demonstrated here, may represent a mechanism by which early postnatal administration of oestradiol accelerates functional brain maturation. Although the nature of this mechanism is still unknown, it is suggested that oestradiol may affect some aspects of cholesterol metabolism which are critical for early myelination. Cholesterol is involved in myelination not only by its accumulation in the free form in the myelin sheath, but also by a possible role in the transport of fatty acids to and from the sites of triglyceride formation and breakdown[6]. Oestradiol has been shown to reduce serum cholesterol in the adult rat, but this has been demonstrated only through some actions of the liver[7]. Rats with diseases characterized by deficient myelination have brains greatly deficient in cholesterol as compared with controls[8]. It is suggested that the effects of oestradiol on myelination are, at least in part, a result of its action on cholesterol metabolism.

Collagen Synthesis in Fibroblasts transformed by Oncogenic Viruses

The synthesis of collagen has been examined in cultures of various cell strains and established cell lines of fibroblastic origin[1–5]. All the strains and most of the established lines synthesized considerable quantities of collagen, but the rate of synthesis varied among the different strains and lines[4,6]. One line, 3*T*3, in contrast to others evolved from the same initial mouse embryo culture, was found to be severely restricted in its ability to synthesize collagen[2,7], while transformants of this line produced by polyoma virus or SV_{40} were able to synthesize collagen at higher rates[7]. It therefore appeared that collagen synthesis in cell line 3*T*3 was repressed and this repression was released by the viral transformation.

These experiments on 3*T*3 and its transformants were carried out on cultures grown in the Dulbecco-Vogt modification of Eagle's medium[8], which itself contained no ascorbic acid, but which was supplemented with 10 per cent calf serum. As fresh calf serum usually contains about 5 μg/ml. ascorbic acid[9], the final medium contained 0·5 μg/ml. or less. Since ascorbic acid is known to be important for collagen synthesis[10,11], the collagen synthesizing ability of cell strains[4,12] and lines has now been tested at higher concentrations of ascorbate. A concentration of 50 μg/ml. is more than sufficient to ensure a maximal rate of synthesis.

The rate of collagen synthesis may be estimated by determining the amount of hydroxyproline accumulated in the cell layer[2] or by exposing the cells to ^{14}C-labelled proline and measuring its incorporation into the non-dialysable hydroxyproline residues of collagen and into the proline residues of all the culture proteins. From the ratio of counts in HyPro to counts in Pro and knowing the abundance of HyPro in collagen and of Pro in the average cell protein, the ratio of collagen (C) synthesized to cell protein (P) synthesized $\left(\frac{\Delta C}{\Delta P}\right)$ during the period of exposure to the labelled precursor can be calculated[3]. This value is an index of differentiated function by the fibroblast.

Table 1 shows that in the absence of added ascorbate the mouse fibroblast line 3*T*6 gives a $\frac{\Delta C}{\Delta P}$ value of 3·5, while cell line 3*T*3 has a $\frac{\Delta C}{\Delta P}$ of only 0·55. Three viral transformants of 3*T*3—*SV*-3*T*3-5, *SV*-3*T*3-10 clone 1 and the doubly transformed *SV*-*PY*-3*T*3-11 clone 11 (ref. 13)—devote a larger fraction of their total protein synthesis to collagen formation than the parent line (up to nearly four-fold). This confirms the results obtained earlier by determining the quantity of collagen accumulated in the cell layer[7].

The relative ability of the cell lines to synthesize collagen is very different if 50 μg/ml. ascorbic acid is added to the medium prior to and during the 12-h period of exposure to the ^{14}C-proline. Line 3*T*6, previously considered to be the best of the lines for collagen synthesis, approximately doubles its rate of synthesis $\left(\frac{\Delta C}{\Delta P} = 6{\cdot}4\right)$, but 3*T*3 undergoes a relatively greater increase, the $\frac{\Delta C}{\Delta P}$ value rising from 0·55 to 7·2. It is therefore clear that in the presence of adequate levels of ascorbic acid, cell line 3*T*3 synthesized collagen as well as any other fibroblast line. In the viral transformants $\frac{\Delta C}{\Delta P}$ was less affected by ascorbate supplementation and was always lower than in the parent cell type (Table 1). The doubly transformed line, *SV*-*PY*-3*T*3-11 clone 11, did not respond to ascorbate supplementation at all; its $\frac{\Delta C}{\Delta P}$ values were comparable with

those found for *L*-929, an established fibroblast line with a long culture history[14] and some neoplastic potential[15]. In other experiments an SV_{40} transformed line derived from a human diploid fibroblast strain[16] was similarly found to be unresponsive to ascorbate supplementation and to have a lower rate of collagen synthesis than the parent strain.

Table 1. COLLAGEN SYNTHESIS BY FIBROBLAST LINES AND THEIR VIRAL TRANSFORMANTS

	HyPro/Pro (%)		$\Delta C/\Delta P$ (%)	
	low ascorbate	ascorbate supplemented	low ascorbate	ascorbate supplemented
3*T*6	9·47	15·4	3·5	6·4
3*T*3	1·60	17·2	0·55	7·2
SV-3*T*3-5	5·35	—	1·93	—
SV-3*T*3-10 clone 1	2·31	13·7	0·80	5·5
SV-3*T*3-5 clone 3	1·88	9·9	0·65	3·8
SV-*PY*-3*T*3-11 clone 11	4·65	4·24	1·66	1·51
L-929	4·56	4·65	1·60	1·66

Collagen synthesis in the transformed cell lines therefore differs from that in the parent cells in two respects: (1) When tested under conditions that allow the maximal rate of collagen formation (adequate ascorbate supplementation) the viral transformants produce less collagen per unit of protein synthesized than the parent line. A second differentiated function, hyaluronate synthesis, also is reduced in transformed 3*T*3 cells[17]. (2) Collagen synthesis in the transformed cells is less dependent on exogenously supplied ascorbate. The first result is consistent with the commonly observed loss of differentiated function occurring in neoplastic cells; the second with an increased metabolic autonomy.

Incorporation of ^{35}S-methionine into Insulin

IN our investigations[1] of the biosynthesis of the *A* and *B* chains of insulin in rats by means of labelled amino-acids, we studied the incorporation of ^{35}S-methionine into that protein, the presence of which has not yet been experimentally demonstrated in insulin. There are some indications in the literature that the amino-acid composition of insulin in rats differs somewhat from that in animals of other species[2–4].

We carried out an investigation *in vivo* of the incorporation of ^{35}S-methionine into insulin of rats. The labelled amino-acid was injected intraperitoneally into the rat (1·2 μc./1·0 g body-weight; spec. act., 530 μc./mg). The animals were killed at various times after the injection. In some experiments insulin was isolated by Petting's method[5]. To purify the admixtures, the isolated insulin was reprecipitated many times at its isoelectric point. The radioactivity of the 'purified' insulin was determined, and results obtained are shown in Table 1.

Table 1. INCORPORATION OF ^{35}S-METHIONINE INTO RAT INSULIN AT VARIOUS TIMES AFTER INJECTION OF LABELLED AMINO-ACID (c.p.m./mg)

Time (min)	40	80	120
Radioactivity (c.)	240	540	680

Due to the possibility that the radioactivity found in insulin after injection of ^{35}S-methionine could be the result of a transformation of the labelled amino-acid into cysteine, followed by incorporation into a molecule of insulin, we determined the amino-acid residues of insulin to which activity belonged. For this purpose, insulin labelled *in vivo* with ^{35}S-methionine was oxidized by Sanger's method[6]; the chains were separated by high-voltage electrophoresis (1·0 mg oxidized insulin was transferred to the electrophoregram, and electrophoresis was carried out in phosphate buffer at *p*H 8·6 and 1,000 V). After eluting the insulin chains with dilute alkali (followed by evaporation under vacuum) the complete hydrolysate of each of the chains was radiochromatographed. The chromatograms of hydrolysates of the *A* and *B* chains of insulin showed radioactivity in the methionine and cysteine positions. In chain *A* 70 per cent of all activity was found in methionine and 30 per cent in cysteine, while in chain *B* the radioactivity of methionine and cysteine was the same (Table 2).

Table 2. DISTRIBUTION OF RADIOACTIVITY BETWEEN METHIONINE AND CYSTEINE RESIDUES IN INSULIN AND ITS *A* AND *B* CHAINS AFTER INJECTION OF LABELLED AMINO-ACID (c.p.m./mg)

Mode of isolation	Amino-acid residues	Insulin	Chain *A*	Chain *B*
Isoelectrical precipitation	^{35}S-methionine	540	350	509
	^{35}S-cysteine	498	150	417
Immunological	^{35}S-methionine	72	—	—
	^{35}S-cysteine	60	—	—

Thus, the data obtained show that ^{35}S-methionine is incorporated into both chains as such, and in addition that its radioactive sulphur resides in the cysteine residues of insulin.

The incorporation of ^{35}S-methionine into insulin in the process of biosynthesis of this protein was also confirmed by isolating insulin immunologically[7]. Complete acid hydrolysis and radiochromatography of the antigen–antibody complex revealed that the radioactivity resided in the methionine and cysteine positions (Table 2). It should be noted that in this experiment 55 per cent of the radioactivity of the original methionine was found incorporated in the cysteine residues of the insulin chains. This finding is in close agreement with the data obtained when insulin was isolated isoelectrically.

The present data indicate that ^{35}S-methionine is incorporated into rat insulin and that it is, in fact, a constituent amino-acid of this protein.

PHYSIOLOGY

Influence of Umbilical Blood Fructose on the Production of Fructose by the Perfused Placenta of Sheep

Several investigations on the sheep placenta, perfused through the umbilical vessels, have shown that this tissue synthesizes fructose and that the initial precursor is glucose[1–4]. These investigations were performed in preparations in which the perfusion circuit was primed initially with maternal blood. Since the maternal blood contains little or no fructose, the admixture of this blood with foetal blood (contained in the placental vessels at the time of incorporation into the perfusion circuit) results in a perfusate which has a lower fructose concentration than was originally present in the foetal blood. Under these conditions, the fructose concentration of the blood recirculating through the placenta typically rises with time. The concentration rises rapidly at first, then more slowly, to reach within 1–2 h a plateau concentration in the range of 100–150 mg/100 ml.; values commonly found in foetal sheep blood. However, in one experiment reported by Alexander, Huggett, Nixon and Widdas[1] some fall was observed following the addition of fructose such that the concentration in the perfusate was greater than this range. Nixon[5] found in the isolated uterus of a pregnant sheep that the placental production of fructose was very much reduced when the fructose concentration in the umbilical arterial blood was similar to that found normally in foetal blood (the uterus was maintained by perfusion circuits through both the uterine and umbilical vessels). Both Alexander[6] and Nixon[5] have suggested that the production rate of 5–10 mg fructose/min previously observed[1] was due to the existence of a subnormal concentration of fructose in the umbilical perfusate. The purpose of the present work was to test this postulate by perfusing sheep placentae by the technique of Alexander, Huggett, Nixon and Widdas[1] with different fructose concentrations in the perfusing blood.

The animals used were Dorset Short-Horn sheep bearing foetuses of 100–120 days, anaesthetized by the spinal administration of procaine. The lower half of the ewe was placed in a saline bath at 38° C, the foetus was delivered by Caesarian section and then detached. Into the umbilical arteries were inserted cannulae fed from a reservoir by a variable speed rotary pump; cannulae inserted into the umbilical veins returned the blood to the reservoir. About 150 ml. of maternal blood was in the extracorporeal circuit. The perfusion pressure was about 40 mm mercury and the rates of blood flow were between 64–136 ml./min. Samples of blood were removed at intervals from the reservoir and the plasma deproteinized with 0·3 N sodium hydroxide and 5 per cent zinc sulphate. The concentration of fructose and glucose in the filtrates was determined by the resorcinol[7] and glucose oxidase[8] methods, respectively. After a period of recirculation the fructose concentration of the perfusate was altered by alternate flushing (venous outflow discarded) and recirculating with the new blood through the placental circulation; this procedure was repeated several times.

The results obtained in two experiments are shown in Fig. 1. In the first phase of experiment *A*, the concentration of fructose rose from 75 to 107 mg/100 ml over a period of 30 min. When, however, the perfusate was replaced by one containing fructose at about 180 mg/100 ml. no production of fructose was apparent. The cessation of fructose production was not due to a deterioration of the preparation because on returning the placenta to a perfusate with a low concentration of fructose, the concentration rose from 48 to 87 mg/100 ml. over 30 min.

In another experiment (not illustrated), which followed the same pattern, the initial 30 min of perfusion was accompanied by a rise in fructose concentration from 108 to 135 mg/100 ml. In the presence of a higher fructose concentration it rose only from 178 to 186 mg/100 ml. over the same period of time; however, on reverting back to a low concentration, the concentration rose from 27 to 100 mg fructose/100 ml. in 30 min.

In the experiment illustrated in *B*, the first phase of the experiment was conducted in the presence of a high fructose concentration followed by a phase at a low concentration and finally back to a high concentration. It will be seen that an increase in the fructose concentration only occurred when the concentration was low.

Using a 'through' perfusion technique, in which the pump drew on a large volume of blood and the outflow from the umbilical veins was collected at frequent intervals in separate containers, it was possible to compute the rate of fructose production in mg/min. In one such experiment where the concentration of fructose in the effluent blood was raised to 172 mg/100 ml. it was found, after a 10 min equilibration at this concentration, that the effluent blood collected in minute fractions had concentrations varying only from 164 to 176 mg fructose/100 ml. with blood flows between 105 and 109 ml./min. From knowledge of these arterio-venous concentration differences and of the rate of blood flow, the production or loss may be calculated. Over the 12 min of the observation period there was a net loss of 23·5 mg fructose which could be attributed to transplacental passage; this can occur at a rate of 0·4–2·0 mg/min in perfused preparations[5].

In all experiments the variations in fructose concentration were independent of the glucose concentration in the perfusate.

Hers[9], on the basis of *in vitro* studies, suggested that both the placenta and the foetal liver were involved in the synthesis of foetal blood fructose. It was suggested that in the placenta the conversion of glucose to sorbitol by aldose reductase (polyol: NADP oxidoreductase) occurred; the sorbitol then passed into the foetal circulation and was converted to fructose by sorbitol dehydrogenase (L-iditol: NAD oxidoreductase) in the foetal liver. While perfusion studies have confirmed that the foetal liver can convert sorbitol to fructose[10], the results of placental perfusion suggest that insufficient sorbitol is liberated from the placenta to substantiate the foregoing hypothesis. How-

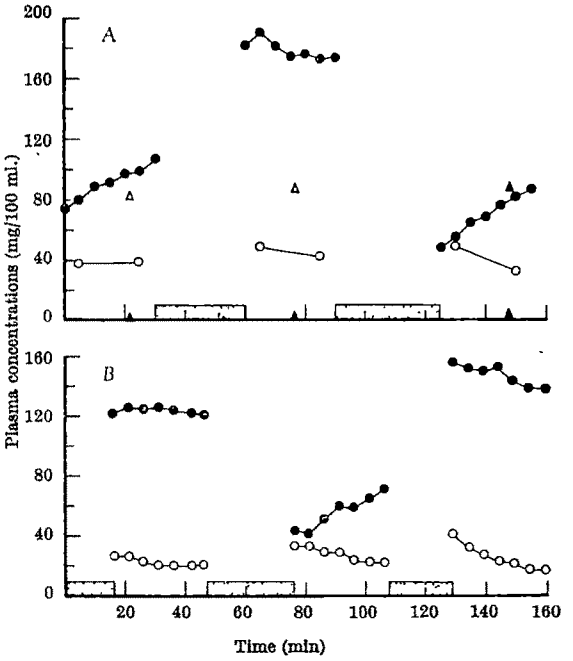

Fig. 1. Production of fructose by two perfused sheep placentae *A* and *B* in the presence of varying concentrations of fructose in the perfusate. The stippled area represents the equilibration period at the new concentration. ●, Umbilical plasma fructose; ○, umbilical plasma glucose, ▲, maternal plasma fructose; △, maternal plasma glucose

ever, it was suggested that a conversion of glucose→sorbitol→fructose occurred entirely within the placental cell and that the cell membrane was permeable to fructose but not to sorbitol[3,4]. The results presented here provide evidence that the foregoing reaction is suppressed by the phenomenon of product inhibition at high fructose concentrations. It is probable, therefore, that the rate of fructose production is governed by the rate at which it is lost from the foetal circulation through transplacental passage and utilization.

Cyanide Excretion in the Rat

Much is now known about the body's metabolism of cyanide within a pattern of normal physiology. The conversion of cyanide to thiocyanate was first demonstrated in 1894 [1] and the enzymatic nature of this reaction was investigated in 1933 [2]). The enzyme system was named 'rhodanese' and it has been found to be specific for free cyanide without action on organically bound cyano groups. This property indicates that the excretion of thiocyanates after the administration of organic nitriles results not from a direct action on the nitrile itself, but from hydrogen cyanide which had first been removed from the nitrile molecule by another mechanism. Although this rhodanese/thiocyanate excretory pathway is considered to be the primary factor in the detoxification of cyanide there undoubtedly exist other pathways by which this may be mediated or assisted[3]. These implicate one-carbon compounds and also reveal that the radiocarbon of $Na^{14}CN$ appears in the methyl groups of choline and methionine and in the ureide carbons of allantoin. Some of it also finds its way into the cyano group of cyanocobalamin. It is known that hydroxocobalamin takes up cyanide avidly to form cyanocobalamin and can protect the experimental animal against lethal doses[4]. Latterly, a further pathway in the detoxification of cyanide has been implicated[5]. This shows that cyanide can combine with cystine *in vitro* to form 2-iminothiazolidine-4-carboxylic acid and that the formation of this acid also occurs *in vivo*. On injection of potassium cyanide subcutaneously into rats, the acid can be isolated from the urine in quantities corresponding to 15 per cent of the dose, although the main excretory product (80 per cent of the dose) is thiocyanate.

Cyanide has been extensively used by various routes as an experimental demyelinating agent[6–8]. Furthermore, it has now been shown that small doses given over a prolonged period of time may produce changes in the central nervous system of the rat without the production of manifest anoxia[9]. This elimination of the anoxic element produced by previous workers in the experimental demyelinating field lends support to the suggestion that a disorder of cyanide metabolism may be implicated in those diseases in which demyelination occurs within a picture of vitamin B_{12} deficiency[10,11].

The mechanism of cyanide demyelination is unknown. Although it has been stated that cyanide is not a cumulative poison[12] it was decided to investigate the excretion of cyanide/thiocyanate over a prolonged period of time. Adult albino Wistar rats were used in the experiment. They were maintained on a standard Oxoid modified diet 41*B*. A subcutaneous injection of 1 mg potassium cyanide was given once weekly for 20 weeks. A basal urine was collected prior to the initiation of the experiment and thereafter urines were collected at monthly intervals for the 24 h immediately following the injections. The estimation of urinary cyanide and thiocyanate was performed by a modification of the method of Aldridge[13]. This utilizes the conversion of cyanide and thiocyanate to cyanogen bromide followed by the determination of the cyanogen bromide by a colour reaction with a pyridine/benzidine reagent. 1·8 ml. N/10 hydrochloric acid had 0·2 ml. urine added and 0·1 ml. bromine water. 0·5 ml. of 2 per cent arsenicus acid was then added to the solution to remove excess bromine. It is important to shake the mixture well after the addition of each reagent. 3 ml. of the pyridine/benzidine reagent was then added and a colour change due to the unknown amount of cyanide and thiocyanate slowly develops and reaches a maximum in 25–30 min. This remains constant for about a further 30 min. It must be emphasized that the stability of the colour is dependent on temperature and allowance must be made for this fact if there is any great fluctuation from 20° C. With each determination, suitable blanks were also prepared by omitting the bromine water. Standard solutions of sodium thiocyanate (containing 3·4 μg/ml.) were made up using volumes of 0·2 ml., 0·5 ml. and 1·0 m. The graph obtained from these is virtually linear and allows the unknown to be calculated directly. If linearity is not established due to temperature distortion then a suitable curve may be drawn and the unknown read from this. The degree of colour change was estimated on a Hilger and Watts Spekker using an Ilford 4 spectral green filter. This reading minus the blank determination was then converted to μg thiocyanate/ml. urine. Urines were stored in the deep freeze after the initial assay and a duplicate performed 1 week later. The mean of these two readings was taken as representing the monthly level for the individual rat.

The results of this experiment show that seven of the eight rats subjected to the procedure gradually re-adapt their metabolic pathways to the injected cyanide so that it no longer appears in the urine as the quantities of thiocyanate found after the initial injection. The monthly output of these seven animals has been expressed as a mean excretion value of the individual mean values obtained (Table 1). One rat (Table 2) proved a notable exception to the general rule although at the conclusion of the experiment its capacity to excrete the cyanide as thiocyanate also appeared to be diminishing. Although many factors influence thiocyanate excretion (body mass, diet, renal clearance, etc.) and for obvious reasons a controlled 24-h sample was not obtainable from the rats used in this experiment, there can be little doubt that a definite trend has been established. The animal which showed a persistently raised thiocyanate excretion may provide a pointer to the fact that the individual rat's tolerance to the same cyanide stimulus shows a marked variation from the neuropathological point of view. Identical histologi-

Table 1. Mean Urinary Thiocyanate Levels expressed as μg/ml. in Seven Experimental Rats at Monthly Intervals

cal changes in the central nervous system are not reproducible in different animals otherwise similar in all respects[9].

The explanation for this disappearance of thiocyanate from the urine in response to the same cyanide stimulus is obviously of theoretical and possibly practical interest. It could be shown that delayed excretion was not the explanation because collecting urine for the second period of 24 h following the injections failed to demonstrate a rise in thiocyanate excretion compared with the figures for the first 24 h presented in this communication. It appeared possible that the cyanide/cystine pathway may have superseded the rhodanese/thiocyanate mechanism and it was obviously important to confirm or exclude this possibility. Cystine may be extremely important as a factor in central nervous system metabolism and it has been shown that this highly insoluble amino-acid can apparently pass through the blood brain barrier and become incorporated in neural proteins[14]. Chromatography of urine for 2-iminothiazolidine-4-carboxylic acid was accordingly performed (Dr. A. S. Azatoor) by the method of Wood and Cooley[5]. This substance could not be identified in the urine of a normal control rat, nor in the urine of a rat which had lost the capacity to excrete cyanide as thiocyanate, nor in the urine from the rat which had substantially retained this mechanism. Although it is claimed that 2-iminothiazolidine-4-carboxylic acid is an innocuous substance the evaluation of the possible effects of repeated injections does not appear to have been assessed in this context. However, our failure to demonstrate it in the urine in this experiment suggests that both the main excretory pathways for cyanide are affected by chronic unphysiological cyanide stimulation. We are left with the possibility that one-carbon compounds or the vitamin B_{12} cycle now play the major part in cyanide metabolism and it is known that the vitamin B_{12} activity of the liver is depleted by repeated injections of cyanide[9,15]. Vitamin B_{12} is stored in the liver as the coenzyme which is cyanide-free and on photolysis yields hydroxocobalamin. Finally, some other unknown degradation product of cyanide metabolism may injure the myelin sheath or cyanide *per se* interfere with some vital intramyelin metabolic pathway.

Although it has been stated that it is not the products of cyanide metabolism which are responsible for cyanide encephalopathy[16] this alteration in the excretory pathway raises all sorts of possibilities which may have important clinical connotations with respect to some disorders of the central nervous system in man.

We thank Dr. John Wilson for granting us a supply of 2-iminothiazolidine-4-carboxylic acid for use in this experiment. One of us (A. D. M. S.) was in receipt of a grant from the Medical Research Council and Peel Research Foundation during the pursuance of this work.

Interoceptive Conditional Response in Cortical Neurones

It has previously been reported[1] that, by presenting simultaneous visceral (splanchnic) and somatic (sciatic) afferent stimuli, evoked potentials can be conditioned in the sensorimotor cortex of the cat. As a continuation of these investigations, we examined cortical units during the same classical interoceptive conditioning procedure to demonstrate the possibility of this type of conditioning in the neurones of the sensorimotor cortex. There are data in the literature on response patterns of cortical units during exteroceptive conditioning in experiments with differing goals[2–4].

Twenty adult cats were anaesthetized with ether and tracheotomized. The left sciatic and splanchnic nerves were exposed, for sequential stimulation in a conditional paradigm. A section of the skull was removed over the sensorimotor area (posterior sigmoid and coronary gyri). In seven of the twenty animals chloralose (10 mg/kg) and local anaesthesia were then substituted for ether. In the other thirteen animals local anaesthesia was combined with immobilization by intravenous gallamine triethiodide and artificial respiration. Stainless-steel microelectrodes were inserted into the brain through a covering layer of agar, which maintained the pressure relations in cerebrospinal fluid and minimized arterial and respiratory pulsations.

The conditioning procedure was as follows: single sciatic shocks (10 V amplitude, 1 or 2 msec duration) were applied every 5 sec. Cells were sought which were either (*a*) silent except during sciatic stimulation (more numerous in chloralose anaesthesia) or (*b*) spontaneously firing, but with changing patterns on sciatic stimulation used as an unconditional stimulus.

When such cells were found responding to sciatic stimulation, the conditioning procedure began: single splanchnic shocks (5–10 V, 1–2 msec) as conditional stimuli were applied every 5 sec. Then splanchnic shocks were 'reinforced' with preceding sciatic stimulation, the conditional stimulus–unconditional stimulus interval being 200 msec. Usually a sequence of ten to forty pairings were presented with an interval of 5 sec between pairs. Finally, the conditional stimulus was presented alone. In each experiment from one to twelve units were 'trained' successively, and the firing pattern photographed.

The units examined were usually not initially responsive to the splanchnic stimulus (conditional stimulus), but fired to the sciatic shock (unconditional stimulus). Spontaneously firing units increased or decreased their firing rate. Altogether, 88 such units were found which changed their firing pattern to sciatic stimulation, and of these 88 units, 25 were capable of being conditioned. Fig. 1 is the record of a cell of a cat under chloralose anaesthesia. The cell, which was unresponsive to splanchnic stimulation before the pairing, gave a clear response after fifty reinforcements with the sciatic stimulus. In the seven animals narcotized with chloralose, 22 units responded on sciatic stimulation, and of these, five cells were conditionable, that is, they did not respond to a splanchnic stimulus unless this was repeatedly paired with sciatic shocks. These units then responded to splanchnic stimulation alone with a response that was strictly correlated with the time at which the sciatic response had appeared in the paired stimulus sequences. The criterion of conditioning was established on the basis of the temporal sequence of the unit firing pattern, and on the ability to 'extinguish' and 'retrain' the responsiveness to splanchnic stimulation.

Several units which fired spontaneously and irregularly before conditioning were not initially responsive to splanchnic stimuli, but became so after sciatic reinforcement. In the thirteen immobilized animals, 66 units were found which changed their firing rate in response to a sciatic stimulus, and twenty of these cells were condi-

tionable. In the majority of these units, or groups of units, the frequency of the firing increased following the sciatic shocks, but in some cases a diminution of the firing rate was observable. In one case this inhibition of the unit activity could be conditioned. In most cases we succeeded in holding the units in good condition for 20–60 min, and in many cells extinction and reconditioning were repeatedly performed. By conditioning the firing pattern of cortical units to splanchnic stimulation, we confirmed earlier data on conditioning of evoked potentials[1], as well as the data of other authors about alteration of unit activity by training[2–6].

Each neurone studied was responsive to sciatic stimulation but not to splanchnic stimulation, although the sensorimotor cortex has been described as the cortical projection area of both sciatic and the splanchnic afferents[7]. After training, however, using the splanchnic nerve stimulation as conditional, and the sciatic nerve stimulation as unconditional stimulus, some units also became responsive to a splanchnic stimulus. Thus, we obtained a relatively simply interoceptive conditioned response (that is, the conditional stimulus was a visceral afferent impulse).

These results may be interpreted as indicating that the neuronal basis of the process of learning might have its origin in a facilitatory state having some resemblance to post-tetanic potentiation[8,9], but clearly differing from it in the requirement for a specific time interval before the initiation of the conditional discharge. It is noteworthy that, after training, the conditional stimulus evokes a cell firing with the same delay as the unconditional stimulus previously applied. This precise timing in the delay of the conditional response may involve some as yet imperfectly understood excitation mechanism, perhaps related to such phenomena as long-lasting inhibitory postsynaptic potentials[10]. Our data do not indicate, however, whether these new neuronal responses arise in or are triggered from a particular cortico-subcortical system, or whether the generation of these delayed spikes is the property of all cortical or subcortical cells.

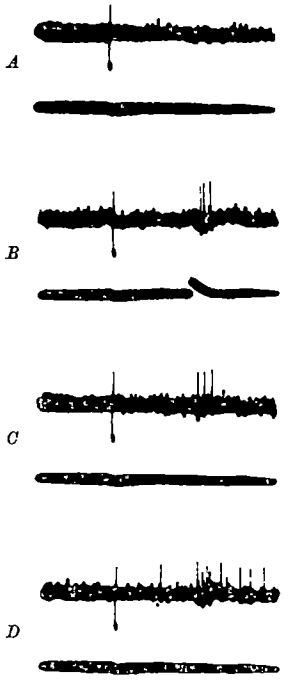

Fig. 1. Conditional responses of a group of cortical units. Conditional stimulus (to splanchnic nerve) appears as artefact in top trace in each case, and unconditional stimulus (to sciatic nerve) as notch in lower trace. Interstimulus interval 200 msec. *A*, Splanchnic stimulation alone initially produces no response. *B*, Paired stimulation of splanchnic and sciatic nerves, with group of 3 discharges to sciatic stimulus *C* and *D*, Induction of responses to splanchnic stimulation alone after paired reinforcements

Such a function in the mammalian brain may be similar to that of the 'pacemaker neurones' described recently in invertebrates[11].

These investigations were supported in part by U.S. Public Health Service grant *NB*–01883.

Aerosol Deposition in the Lungs of Space Travellers

The deposition of aerosols in the lungs of man during breathing constitutes an important mechanism for the entry of toxins or pathogenic organisms to the body. The respiratory tract is protected by an efficient ciliary mechanism for the rapid removal of particles deposited in the upper airways. Particles reaching the alveolar regions are removed more slowly. There are three mechanisms whereby inhaled particles are deposited on the walls of the airways—inertial impaction, sedimentation by gravity, and diffusion due to Brownian motion. The dimensions of the airways are such that large particles are deposited in the upper airway and have no opportunity of reaching the alveoli.

In the absence of gravity, as in an orbiting spacecraft, one may anticipate that particles normally deposited in the lungs by sedimentation (principally those particles of 1–8μ diameter) will be exhaled again with no deposition. Under the conditions of a reduced gravitational field as on the Moon an important distinction arises. While the deposition of particles in the range 1–8μ diameter will be less than normal, the particles of this size which are deposited will do so in a deeper region of the airways than normal. One effect of a reduced gravitational field may thus be to allow the access of large particles to the non-ciliated alveolar region of the lung. Particles of this size are important in the airborne spread of infection because they include the droplet nuclei carrying bacteria which are produced by the act of coughing or talking. The importance of this hazard to astronauts remains to be established.

Motor Unit in Old Age

Decrease of muscular efficiency, fatigue and slowness of motor reactions are considered to be typical consequences of old age. No convincing evidence, however, has been brought forward as yet for the assumption that these motor deficiencies in old age are due to regressive changes, such as loss of nerve cells, disturbances of neuromuscular transmission or to degenerative atrophy of the muscle fibres themselves[1,2].

In many respects the muscles of an old animal resemble denervated muscles in their metabolic reactions. For example, the characteristic differences of metabolism between muscles with different function are lost[3] and proteolytic activity increases[4] in both denervated muscles and muscles of an old animal. On the other hand, the increased proteosynthesis in spinal motor neurones after nerve interruption which appears to be a characteristic reaction of a nerve cell to interruption of its cell process[5] is missing or very much delayed in the motor neurones of an old animal[6]. This corresponds to the delayed latent period (that is, the time before re-innervation of the peripheral nerve stump begins) during the regeneration process in an old animal[7] and there is also a considerable delay of recovery of muscle proteins of an old animal once re-innervation of muscle has started[7]. Thus, the atrophy of muscle and the metabolic disturbances observed could be due to central (regressive changes or loss of motor neurones) or peripheral (atrophy and/or degeneration of muscle fibres) changes. In both cases a decrease in the number of muscle fibres could be expected. Indeed, the total number of muscle fibres in the soleus muscle of adult rats has been found to decrease from 2,357 ± 78 (ref. 8) in adult (4-month-old) rats to 1,758 ± 39 in the soleus of old (2-year-old) rats.

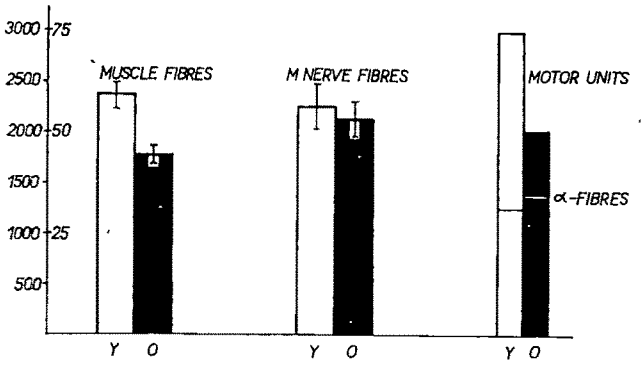

Fig. 1. Changes in total number of muscle fibres (left-hand side of ordinate) in soleus muscle of rats. Motor nerve fibres, α-nerve fibres, and motor units (right-hand side of ordinate) innervating the soleus muscle in young (*Y*) and old (*O*) rats

To determine the number of motor nerve fibres and the size of the motor unit innervating the soleus, dorsal roots L_3—S_2 were cut on one side in six animals and the motor nerves innervating the soleus muscle were removed 14–30 days later. Their number and diameters were determined in histological preparations stained using a modified Weigert method following fixation with 1 per cent osmic acid. The total number of motor nerve fibres innervating the soleus of old animals was 115 ± 2·31, compared with 120 ± 3·8 in adult animals. The number of α-motor fibres (more than 4μ) was 35 in the nerves of old, and 32 in those of adult animals. The histogram of the motor nerves of old animals showed a loss of bimodality, that is, only one maximum for fibres of 8·5–10μ instead of the two maxima (2·5–4μ and 8·5–10μ) found in the motor nerve fibres of adult animals, but no other changes in size distribution of the motor nerve fibres could be seen. Thus, it can be assumed that there is no loss of motor nerve cells in the spinal cord of an old animal. Due to loss of muscle fibres in muscles of an old animal, however, the size of the motor unit decreases by 33 per cent, that is, from 74 in muscles of adult rats to 50 in muscles of an old animal. It appears that this decrease in the size of the motor unit is due to peripheral changes and this assumption is substantiated by the changes in the sub-neural apparatus of the end plates as indicated by their cholinesterase activity. This shows diffusion, irregularity and granular fragmentation of the end plate structures. Beside random degeneration of the end plate, some terminal regeneration also occurs, which leads to irregularities in the pattern of innervation of the muscles of an old animal[9]. It remains to be seen how these peripheral effects are related to the previously mentioned disturbances of nerve-cell function[6,7].

The random degeneration and regeneration of end plates may explain the increased duration of the action potential in muscles of an old animal[10] and also the absence of 'denervation fibrillation' in muscles during old age.

We may conclude that, during old age, no loss of motor neurones occurs in the spinal cord of an old animal but that random degeneration of end plates leads to a loss of muscle fibres which results in a decrease in size of the motor unit.

PHARMACOLOGY

Effects of Synthetic Angiotensin on Plasma Free Fatty Acid and Blood Glucose-levels

Recently, a number of investigators reported that the vasoactive peptides with smaller molecular weights, oxytocin, vasopressin and pitressin, decrease or increase plasma free fatty acid (FFA) levels in animals[1] and human subjects[2–4]. These peptides were also found to cause mobilization of FFA from the rat epididymal adipose tissues *in vitro*[5–8]. The present investigation was undertaken to examine the effects of a potent vasoactive peptide, angiotensin, on the plasma FFA and blood glucose-levels in dogs.

Six male dogs, fasted for 12 h, were anaesthetized with the intravenous administration of sodium pentobarbital (30 mg/kg). Mean systemic arterial pressure and heart rate were measured using techniques described previously[9]. To keep the activity of the sympathoadrenal system reasonably constant[10], 1 h was allowed to elapse from the time of the completion of the experimental preparation to the beginning of the measurements of the various parameters. Synthetic angiotensin ('Hypertensin') was infused intravenously at a rate of 0·1 μg/kg/min for 1 h. Blood samples were drawn from a femoral artery. The determination of blood sugar and plasma FFA levels were made in duplicate using the methods described by Nelson[11], Somogyi[12], Dole[13] and Trout *et al.*[14], respectively.

The results of the effects of angiotensin on plasma FFA and blood glucose levels are summarized in Table 1. Angiotensin always decreased heart rate and significantly increased mean systemic arterial pressure. Furthermore, angiotensin always significantly decreased both plasma FFA and blood glucose levels.

Table 1. Effects of the Continuous Intravenous Administration of Angiotensin (0·1 μg/kg/min) on Heart Rate, Mean Systemic Arterial Pressure, Blood Sugar-levels and Free Fatty Acid-levels

	Control	Angiotensin
Heart rate (beats/min)	143 ± 6	123 ± 4 ($P < 0.001$)
Mean systemic arterial pressure (mm mercury)	136 ± 6	167 ± 8 ($P < 0.025$)
Blood glucose levels (mg per cent)	128 ± 8	100 ± 5 ($P < 0.01$)
Plasma free fatty acid levels (μequiv./l.)	335 ± 21	156 ± 24 ($P < 0.005$)

Numerical values denote the mean ± standard error of the means of 6 dogs.

The effects of synthetic angiotensin on plasma FFA-levels and blood glucose-levels observed in the present investigation were essentially similar to those found previously with the other vasoactive peptides, pitressin and oxytocin[1-3]. Although the metabolic effects of pitressin and oxytocin have been referred to as 'insulin-like actions' by previous workers[1,5,6], Krahl[15] found that these vasoactive peptides do not promote protein synthesis. It is possible that angiotensin may also act in a similar fashion on protein synthesis. Recently, Feldberg and Lewis[16] observed that angiotensin stimulates directly catecholamines from the adrenal medulla in the cat. It is expected that the increased catecholamine secretion following the administration of angiotensin results in increases in plasma FFA and blood glucose-levels[13,17]. However, the results obtained from the present experiments do not coincide with this hypothesis in dogs. It is possible, however, that angiotensin may directly decrease plasma FFA- and blood glucose-levels, and these direct metabolic effects may overpower the indirect effects of catecholamines following the administration of angiotensin. Recently, Colville *et al.*[18] found that the cholinesterase inhibition with neostigmine lowered plasma FFA in dogs. Angiotensin increases arterial blood pressure and reflexly stimulates the parasympathetic nerve fibres. Hence, it is possible to suggest that angiotensin decreases plasma FFA by a similar manner. At present, however, the precise biochemical and physiological mechanisms responsible for the changes in plasma FFA- and blood glucose-levels are not clear. The *in vitro* investigation is indicated to elucidate this problem.

Effect of Propranolol on the Peripheral Vascular Bed

A NEWLY synthesized compound, propranolol, was found to be a very potent, β-receptor adrenergic blocking agent[1]. Since the drug blocks the vasodilator (β-receptor stimulating) effects of catecholamines without affecting the vasoconstrictor (α-receptor stimulating) property, propranolol should be expected to cause the vasoconstriction of the peripheral vessels. However, Prichard and Gillam[2] recently found that propranolol lowered arterial blood pressure significantly in hypertensive patients. The present investigation was undertaken to examine the effect of propranolol on the peripheral vascular bed.

Dogs weighing between 20·5 and 25·0 kg were anaesthetized with sodium pentobarbital (30 mg/kg). In open chest dogs, a femoral artery was perfused with arterial blood at a constant and known rate by means of a Sigmamotor pump as described previously[3]. Systemic arterial pressure and femoral arterial perfusion pressure were measured continuously with Statham pressure transducers (*P23AA*). In this set-up, the effect of the drug on the peripheral vascular resistance was evaluated readily by the changes in the perfusion pressure. Heart rate and myocardial contractile force were measured continuously with an EFM tachometer and with a Walton–Brodie strain gauge arch[4,5] which was sutured on the right ventricular muscle. All parameters except heart rate were recorded continuously with an EFM recorder (*DR* 8).

As shown in the third part of Fig. 1, the effect of the intra-arterial injection of propranolol (25 μg/kg) on the femoral arterial perfusion was biphasic. The drug initially decreased the perfusion pressure markedly and rapidly but, within 1 min, the pressure began to increase and usually stabilized at a level slightly higher than control within 2 min. Since the femoral arterial blood flow was kept constant by means of a Sigmamotor pump and the systemic arterial pressure remained essentially unchanged throughout a period of the experiment, these biphasic changes in the perfusion pressure indicate that propranolol initially caused a transient vasodilatation and later a sustained vasoconstriction. As seen in the fourth part of Fig. 1, propranolol blocked completely the vasodilating effect of the intra-arterial administration of isoproterenol (0·01 μg/kg). However, the repeated administration of 25 μg/kg of propranolol caused an essentially similar degree of vasodilating effect as indicated by the decrease in the perfusion pressure. This effect was not modified by the intra-arterial injection of dichloroisoproterenol (0·8 mg/kg) or atropine (0·05 mg/kg). The magnitude of vasodilatation induced by propranolol was essentially proportional to the dose given, but that of the subsequent vasoconstriction became less and less striking with repeated administrations of the drug (25 μg/kg). However, much larger doses (more than 250 μg/kg) of propranolol, which significantly decreased systemic arterial pressure, markedly increased the femoral arterial perfusion pressure[6]. Qualitatively similar results were also obtained on the effects of propranolol on the peripheral vascular beds in the brachial artery.

From the present investigation, it seems evident that the intra-arterial administration of a small dose of propranolol dilates the regional arteries transiently before it constricts

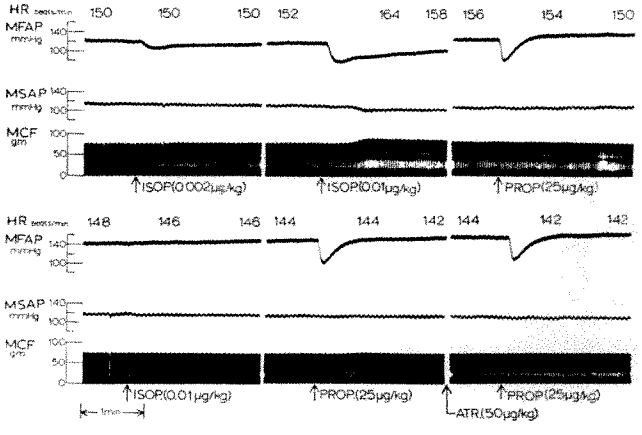

Fig. 1. Effect of propranolol on the peripheral circulation. *HR*, *MFAP*, *MSAP* and *MCF* denote, respectively, heart rate, mean femoral arterial perfusion pressure, mean systemic arterial pressure and myocardial contractile force of the right ventricle. *ISOP*, *PROP*, and *ATR* denote, respectively, isoproterenol, propranolol and atropine. These drugs were injected in the femoral artery. The femoral artery was perfused with arterial blood at a rate of 135 ml./min throughout a period of the experiment

the vessels by its β-receptor adrenergic blocking action. The initial vasodilatation is apparently due neither to stimulation of adrenergic β-receptor nor to that of cholinergic vasodilator fibres[7]. On the other hand, the administration of larger doses of propranolol constricts markedly the regional arteries mostly by the indirect stimulation of adrenergic α-receptor which is mediated through the increased reflex sympathoadrenal activities[6,7]. Obviously, the larger doses of propranolol always depress myocardial contractility and reduce stroke volume and cardiac output, thereby decreasing mean systemic and pulse pressures to elicit the cardiovascular reflexes[6,8,9]. Very recently, Prichard and Gillam[2] reported that propranolol may be useful for the management of essential hypertension. Although propranolol initially decreases the peripheral vascular resistance, the duration of the action is extremely short to be effective in the treatment of essential hypertension. Furthermore, we reported[6] that the doses of propranolol, which block effectively the adrenergic β-receptor, not only increase total peripheral resistance but also depress the ventricular function curve[10]. From the aforementioned reasons, it is rather difficult to comprehend the precise pharmacodynamic mechanism through which propranolol clinically alleviates essential hypertension.

HISTOLOGY

Histochemical Demonstration of the Resorption of Xylose from Small Intestine

The high solubility of monosaccharides makes the topochemical demonstration of these substances in animal cells and tissues very difficult. In 1948, Okamoto, Kadota and Aoyama[1] described a method for the histochemical demonstration of sugars in tissue which is based on the insolubility of barium–glucose and barium–lactose in methyl alcohol. Gomori[2] showed that the specificity of this method was not sufficiently tested and the topochemical demonstration was unlikely to be very accurate. Müller[3] carried out tests with filter paper in order to discover whether it was possible to show the distribution of glucose by this method, and found a high specificity after fixation in a saturated solution of barium hydroxide in methyl alcohol. In experiments with animal tissues fixed at −10° C for 24 h he obtained a strong reaction in liver cells, but kidney cells were negative. Using freezing substitution with saturated barium hydroxide–methyl alcohol solution, Geyer[4] described the distribution of glucose in the kidney, and Stiller[5] was able to demonstrate the presence of glucose in the mature human placenta using this modification. Ehrenbrand[6] used cold microtome sections for the localization of glucose and probable galactose in the secreting mammary gland of hamsters.

Recently we succeeded in demonstrating solutions of monosaccharides, especially stereoisomeric sugars such as glucose, mannose and galactose, as arabinose and xylose or fructose. The solutions were dipped on filter paper and fixed with the saturated barium hydroxide–methyl alcohol solution at −22° C and were sharply localized up to concentrations of from 0·08 to 0·005 per cent. In contrast, sugar phosphates are difficult to demonstrate and the results of this experience suggest that disturbances of sugar phosphates by the topochemical demonstration of monosaccharides under physiological conditions are improbable.

Experiments were undertaken using white mice previously starved for 24 h and fed on 10 per cent xylose solution in order to study the resorption of sugars from the small intestine. The cryostat technique was used, in conjunction with fixation of the sections, in cold (−22° C) saturated barium hydroxide–methyl alcohol solution. It proved impossible to localize this sugar topochemically in the cells of intestine. After this, better results were obtained by modifying the fixation procedure and using a saturated solution of strontium hydroxide in methyl alcohol. First, tests were carried out on filter paper. Fig. 1 demonstrates the difference between the behaviour of xylose after fixation in saturated barium hydroxide–methyl alcohol solution at −22° C (Fig. 1*a*) and after fixation in saturated strontium hydroxide–methyl alcohol under the same conditions. These experiments showed a sharp localization and a deep blackness after fixation in strontium hydroxide–methanol and treatment with an alcoholic silver nitrate solution (Fig. 1*b*). Application of this modification to tissue samples from mice fed xylose resulted in the topochemical demonstration of xylose resorption.

Various stages of the resorption can be shown. Within the epithelial cells of the mucosa, granules in the supranuclear zone first become visible. Later these granules can be shown throughout the whole of the cytoplasm of the cells (Fig. 2). At the bases of the crypts the reaction is stronger. This is the main pattern, but occasionally the intercellular spaces reacted more strongly than did the cytoplasm of the cells. Afterwards, a diffuse positive reaction was observed in the stroma of the villi and the endothelial cells of the capillaries also reacted positively.

The results make it clear that xylose can be shown topochemically by this method during the process of resorption (the controls, which were not fed xylose, were negative). The developments reported here also show that xylose may enter mucosa cells in various stages. Furthermore, it is clear that the majority of the resorption of xylose from the intestine is achieved in a percellular way, and that less than half is achieved in an intercellular one.

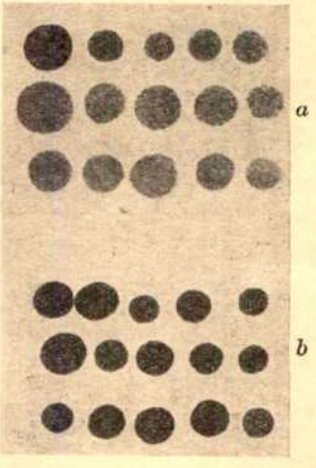

Fig. 1. Comparison of fixation of xylose on filter-paper at −22° C. (*a*) Fixation in saturated barium hydroxide–methyl alcohol; (*b*) fixation in saturated strontium hydroxide–methyl alcohol. Concentrations of xylose range from 10 per cent to 0·0006 per cent, beginning in the upper left-hand corner of each part. The concentration of xylose in each spot is half that in the previous spot

Fig. 2. Demonstration of xylose at a later stage of the process of resorption

It is possible that a more complete study including early stages of sugar transfer might show further differences in the process of resorption, especially in various parts of the intestine.

IMMUNOLOGY

Effect of Large Quantities of Homologous Globulin on Cells of the Plasma Series in Lymphatic Nodes

THE homoeostatic mechanisms acting in the lymphoid cell system are still obscure. The hypothesis of mutual feed-back humoral interrelationships between the various mesenchymal cell derivatives is being tested in this laboratory[1,2]. Thymus suppresses the proliferation of plasma cells and directly or indirectly stimulates the maturation of these cells. This is the cause of the delayed and prolonged antibody formation in animals thymectomized at birth[3]. This communication describes experiments which we undertook to discover whether excess globulin suppresses the multiplication of plasma cells.

Non-inbred albino rats were used. Total globulins, as well as albumin fraction, were sedimented from the same lot of pooled rat sera by 50 per cent saturation with ammonium sulphate, dissolved in distilled water, and dialysed against physiological saline at *p*H 7. The globulin and albumin were filtered through the Chamberland candle L_3. The protein nitrogen was estimated in the solutions of globulin and albumin. The protein content was equalized in the samples of both solutions before administration to the animals.

The general schedule of experiments was as follows. The rats were divided into three groups. The first received globulin, the second albumin, the third saline. In all groups, the rats were injected subcutaneously in the footpad of the right hind leg with 0·1 Freund adjuvant mixed with an equal quantity of saline. In experiments Nos. 3 and 5 the rats received 0·1–0·5 ml. globulin solution (or albumin solution or saline) in the right footpad, and 2·4–4·5 ml. intraperitoneally, before injection of the Freund adjuvant, and three times daily from 3 days thereafter. The amount of protein injected into each rat was 1,012 mg in experiment No. 3 and 884 mg in experiment No. 5. In experiment No. 4, globulin (and albumin and saline respectively) were injected into the hind right leg on the fifth day after the administration of Freund adjuvant. 1 ml. was administered six times over a period of 2 days (total, 277 mg). The rats were killed, and prints of the cut surfaces of various lymph nodes were made on coverslides, fixed with methanol and stained with azureosin. In each preparation, a differential cell count was made in thirty fields of vision (130–150 cells per field), as described by Pokrovskaya *et al.*[4]. In all experiments there was some suppression of plasma cells in popliteal and lumbar (retroperitoneal) lymph nodes in the groups of rats injected with globulin as compared with the rats injected with albumin.

A statistically significant reproducible effect was noted in the lymph nodes lying behind the thymus ('parathymic') (Table 1). There was a marked suppression of cells of the plasma series in these lymph nodes, even in experiment No. 4, in which proteins were injected in the hind leg only.

These experiments show that globulin and albumin act on cells of the plasma series in different ways. The suppressive action of excess globulin in regulating the multiplication of cells of the plasma series is, perhaps, a basic homeostatic mechanism. It is still debatable whether this action of blood proteins on plasma cells is direct, or whether it is mediated by various systems. There is, as yet, no satisfactory explanation as to why the parathymic lymph nodes are more susceptible to homologous blood proteins than other lymph nodes. It is interesting to note that, in the course of accidental involution of lymphatic organs after injection of cortisol, the parathymic lymph nodes behaved in a different manner from the other lymph nodes (unpublished data).

Experiments using paper electrophoresis showed that daily injection of 14 ml. blood globulin for 4 days did not lead to hyperglobulinaemia: 12 h after the last injection the level of plasma globulin was quite normal. This is an indication of the existence of a strong homoeostatic mechanism for the elimination or destruction of excess of globulin.

Table 1. EFFECT OF HOMOLOGOUS SERUM GLOBULIN AND ALBUMIN ON PLASMA CELLS IN THORACIC PARATHYMIC LYMPH NODES*

Cells	Experiment No. 3					Experiment No. 5					Experiment No. 4				
	Groups of rats injected with					Groups of rats injected with					Groups of rats injected with				
	Globulin 1	Albumin 2	P_{1-2}†	Saline 3	P_{1-3}‡	Globulin 1	Albumin 2	P_{1-2}	Saline 3	P_{1-3}	Globulin 1	Albumin 2	P_{1-2}	Saline 3	P_{1-3}
Reticular	243	275	—	266	—	410	289	999	431	—	225	247	—	246	—
Blasts	89	106	983	36	—	59	87	789	22	930	21	40	930	39	816
Plasma blasts	18·4	30·6	716	16·5	—	16	40	860	9	430	3·6	11	984	6·5	644
Plasma cells	216	458	962	264	730	165	420	995	278	920	117	407	999	247	878

* The table shows the absolute quantity of the respective kind of cells.
† P_{1-2}, Significance between quantity of cells of group 1 (globulin injected) and group 2 (albumin injected).
‡ P_{1-3}, Significance between quantity of cells of group 1 (globulin injected) and group 3 (saline injected).

No doubt, future experiments will elucidate the relationship of this phenomenon to the suppression of antibody formation in the primary response by means of passive administration of the specific homologous antibody[5,6].

Sensitization of Mice with Human IgA

It is well known that an increased vascular permeability produced by various agents can be visualized by the leakage of intravenously administered dye through the affected vessels. The vascularity and high histamine and serotonin content of mouse ears[1] suggested that these organs might be useful in the visualization of *in vivo* antigen–antibody reactions. While investigating the ability of intravenously administered pollen extracts to induce blueing of the ears of mice[2], Kind *et al.* also found that mice sensitized with bovine serum albumin (BSA) developed blueing of the ears when later challenged intravenously with BSA and Evans blue dye. When blueing of the ears was produced in normal mice by the intravenous injection of BSA, rabbit anti-BSA and dye, no latent period was found to be necessary for the 'fixation' of antigen or antibody[3]. Indeed, in mice, maximal incidence of anaphylaxis with rabbit antibody can be obtained by injecting antibody and antigen intravenously in rapid succession[4]. The apparent absence of a requirement for tissue fixation in mice suggested that blueing of the ears in anaphylactic mice might be useful for detecting such proteins as normal human IgA or myeloma IgA, which will not sensitize guinea-pig skin for reverse passive cutaneous anaphylaxis probably because of the lack of fixation sites on such molecules[5].

Swiss–Webster female mice weighing 17–20 g were inoculated intravenously with 0·05 ml. of various dilutions of normal human serum (NHS). One hour later the animals were again injected intravenously with 0·1 ml. of goat anti-human IgA (Hyland Laboratories, Los Angeles, California) and 0·2 ml. of 0·5 per cent Evans blue dye. The anti-IgA serum was found by immunoelectrophoresis to develop a single, strong precipitin line with whole human serum. The data in Table 1 indicate that as little as 0·05 ml. of a 1 : 20 dilution of NHS was able to sensitize mice. The concentration of IgA in normal human serum is 150 to 400 μg/ml. (ref. 6). Since no pure IgA was available and since an anti-serum to IgA, although absorbed to make it specific, might contain small amounts of antibodies to other serum components, it was necessary to demonstrate by additional experiments that the observed blueing of the ears was actually due to IgA–anti-IgA interaction. The data in Table 1 indicate that an IgA myeloma serum which contained about ten times more IgA than did NHS could sensitize mice for blueing of the ears at a dilution of 1 : 200 in contrast to NHS, which could not be diluted more than 1 : 20 and still retain its ability to sensitize. In gel-diffusion investigations this IgA myeloma serum produced a single precipitin band with anti-IgA and this band fused (reaction of identity) with the band formed by NHS and anti-IgA. The data in Table 2 indicate that cord

Table 1. Sensitization of Mice with a Normal Human Serum and with an IgA Myeloma Serum

Mice sensitized intravenously with: 0·05 ml. normal human serum (NHS)	Mice challenged intravenously 60 min later with: 0·1 ml. goat anti-IgA plus 0·2 ml. of 0·5 per cent Evans blue dye	No. of mice reacting (blue ears) Total No. challenged 10/16

NHS 1 : 20	,,	2/6
NHS 1 : 50	,,	0/5
Saline	,,	1/20
0·05 ml. IgA myeloma serum (diluted 1 : 200)	,,	8/14
0·05 ml. IgA myeloma serum (diluted 1 : 500)	,,	0/5
0·5 ml. IgA myeloma serum (diluted 1 : 200)	Dye plus saline	0/5
0·05 ml. NHS	,,	0/5

Table 2. Sensitization of Mice with Cord and Maternal Sera

Mice sensitized with:	No. of mice reacting (BE)* / No. of mice tested	IgA present in serum (by immunoelectrophoresis)
maternal serum †	4/8	+
cord serum	0/6	−
maternal serum	2/3	+
cord serum	0/5	−
maternal serum	4/5	+
cord serum	1/5	−
maternal serum	3/4	+
cord serum	1/5	−

* Mice injected with 0·05 ml. of cord or maternal serum were challenged 60 min later with 0·1 ml. of goat anti-IgA and 0·2 ml. of 0·5 per cent Evans blue dye. Control mice injected with antiserum plus dye or antigen plus dye produced no blueing of the ears (BE).
† Four different pairs of cord and maternal sera were tested.

sera which contain no IgA detectable by immunoelectrophoresis (as previously demonstrated by Allansmith *et al.*[7]) rarely sensitized mice for blueing of the ears with goat anti-IgA, whereas maternal sera shown to contain IgA by immunoelectrophoresis were effective sensitizers. Mice failing to give blueing of the ears after injection of cord serum, goat anti-IgA, and dye were later challenged intraperitoneally with goat anti-IgG. Blueing of the ears occurred in all animals tested[8]. Although no pure IgA was available for these investigations, the results obtained with an IgA myeloma serum (greatly increased sensitization) and with cord sera (greatly reduced sensitization) strongly suggest that human IgA can sensitize mice. Since it has been shown that human IgM, like human IgA, will not sensitize guinea-pig tissues[8], the method described here may also be useful for quick detection of human IgM proteins or their fragments.

I thank Dr. E. C. Franklin for the myeloma serum, and Dr. Elizabeth B. Connell for the maternal and cord sera. This work was supported by Clinical Research grant *AI*–05861 from the National Institute of Allergy and Infectious Diseases.

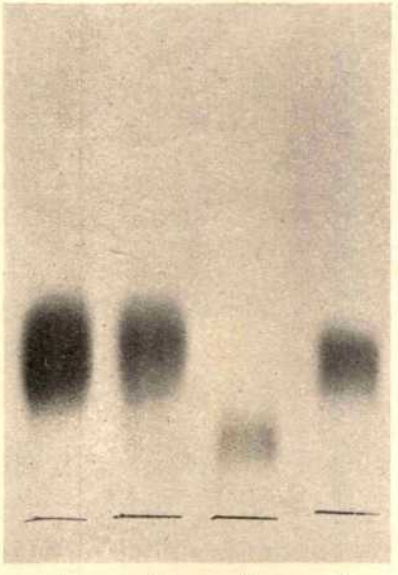
Electrophoretic Behaviour of *H* and *L* Chains of Human Serum and Colostrum Gamma-globulin

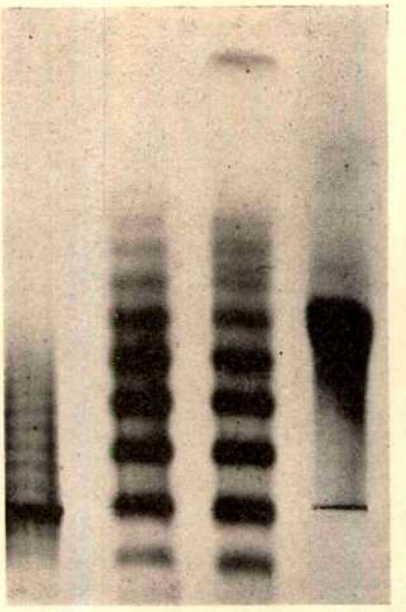
Dissociation of gamma-globulin molecules by reduction in urea with such thiol reagents as mercapto-ethanol and thioglycolate[1,2], or in neutral aqueous solution[3], or by *S*-sulphonation[4,5], allows the identification of two types of polypeptide chain, called *H* (*A*) and *L* (*B*), which may be separated by gel filtration.



The *L* chain is the carrier of antigenic and allotypic determinants common to all types of immunoglobulins; its high degree of heterogeneity is apparent on starch-gel electrophoresis in formic acid and urea[6] and especially in glycine and urea. This mode of electrophoretic separation allows separation of *L* chains of all investigated animal species into approximately ten components, which, according to Cohen and Porter[7], probably differ in amino-acid composition.

In contrast to this, *H* chains are the carriers of the properties characteristic for each class of immunoglobulins. The heterogeneity of this chain is apparent from these characteristic properties and from the fact that it contains two N-terminal amino-acids[8]. However, electrophoretic separation of this chain into more components has not yet been achieved, although its extensive diffusion zone, which has the same mobility as the initial gamma-globulin, confirms its heterogeneity.

The experiments reported here were designed to investigate the differences in electrophoretic behaviour of polypeptide chains of gamma-*G* globulins in human blood serum and of the immunoglobulin of human colostrum, which was found to correspond in electrophoretic properties to serum gamma-*A* globulin, but which carries antigenic determinants specific both for gamma-*A* and gamma-*G* serum globulins[9,10].



H- and *L*-type chains were prepared from immuno-electrophoretically homogeneous preparations of gamma-globulin[11] by *S*-sulphonation for 20 h (ref. 5) in 0·5 M ammonium buffer, *p*H 8·6, containing cupric ions. Isolation of chains was performed on 'Sephadex *G*-100' columns in 6 M urea and 0·05 M formic acid. Solutions of the chains were neutralized, transferred to 0·05 M ammonium carbonate on 'Sephadex *G*-25' and lyophilized. Units prepared in this way were found to be quite soluble in the buffers normally used.

Fig. 1 shows the analysis of *H* and *L* chains of human serum and colostrum gamma-globulin by electrophoresis in starch gel containing formic acid and urea. It is clear that the *L* chain from serum and colostrum forms zones quite similar in shape and mobility, while the migration of colostrum *H* chain is apparently slower than the migration of *H* chain from serum gamma-globulin. These findings indicate that the *H* chains of human colostrum immunoglobulins behave very similarly to the *H* chains of serum gamma-*A* globulin. However, striking differences

Fig. 2. Starch-gel electrophoresis in 0·035 M glycine and 8 M urea. *A*, *H* chain of serum γ-globulin; *B*, *L* chain of serum γ-globulin; *C*, *L* chain of colostrum γ-globulin; *D*, *H* chain of colostrum γ-globulin

were found in the analysis of the same material by starch-gel electrophoresis, using 0·035 M glycine and 8 M urea. Fig. 2 shows that this procedure separated *L* chains into the usual number of zones, two of which migrate cathodically, while one remains at the start and seven migrate to the anode. Comparing the spectra of both chains tested, they were found to be very similar, with the exception of the fifth and sixth zone, which doubled in the direction of the anode in the case of colostrum chain, and moreover another intensive, very fast-moving zone was found in this colostrum chain, which is absent in serum material.

As with the *L* chain, we succeeded in separating the *H* chains of serum gamma-globulin into a number of zones, the character and mobility of which are quite different. These zones are narrow, with relatively small differences in electrophoretic mobility, showing that these components are closely related. In contrast to this, the same chain, isolated from colostrum immunoglobulin, formed one wide zone with greater mobility than the serum *H* chain, and moreover showed only a trace of one faster and one slower zone.

Separation of the *H* chain of human serum gamma-globulin into individual fractions by glycinated starch-gel electrophoresis has, until now, been unsuccessful[7]. The successful separation of the *H* chain into ten fractions in our experiments may be imputed to the aforementioned relatively gentle method of preparing the chains. The possibility of separating the *H* chain into fractions is not limited to the human material; similar results were obtained with pig material, and this is considered to be further evidence for the high heterogeneity of this chain. The experiments of Poulik and Shuster[12], who succeeded in fractionating papain *F* fragment (part of the *H* chain) into ten to thirteen components, support the supposition that this heterogeneity is not an artefact caused by the method of preparation of the chains. In contrast to this, *H* chains of colostrum immunoglobulin seem to be less heterogeneic, as they only form one wide zone. This is in agreement with the assumption that the mammary gland selects only a part of heterogeneic mixture of blood serum immunoglobulins[13].

Differences between *L* chains of serum and colostrum gamma-globulin, expressed by the presence of a fast-

moving zone only in the colostrum material, confirm that even the *L* chains of the preparations compared are not quite the same.

We thank Dr. J. Šterzl for his advice, and Mr. J. Dušek for technical assistance.

PATHOLOGY

Phosphorylase Activity in Megakaryocytes

In 1956, Scavo and Andres[1], and later others[2–4], reported that glycogen in megakaryocytes was decreased in chronic idiopathic thrombocytopenic purpura (ITP) with megakaryocytic hyperplasia before splenectomy. Also, some of these investigators[1,2] showed that megakaryocytic glycogen increased after splenectomy and that the increase coincided with the appearance of budding megakaryocytes and numerous platelet masses in bone marrow. Jamra and Lorenzi[5], however, following Daniell's[6] system for semi-quantitating megakaryocytic glycogen, noted that in presplenectomy patients with ITP there was an increase in large coarse PAS positive glycogen granules and concluded that this histochemical finding might prove to be pathognomonic of ITP with megakaryocytic hyperplasia. Because of the importance of phosphorylase, required for the initiation of glycogenolysis, it was decided to determine if the large masses of glycogen in megakaryocytes in this condition might be cumulative secondary to a relative phosphorylase deficiency, that is, an acquired megakaryocytic phosphorylase deficiency glycogenosis.

Quaglino and Hayhoe[7] described a method for the histochemical detection of haemic phosphorylase based on a modification of the technique originally developed by Takeuchi and Kinoshita[8]. As a degradative enzyme, phosphorylase is specific for the phosphorylytic cleavage of the -1-4 linkages of glycogen to yield glucose-1-PO_4. The reaction is apparently irreversible *in vivo*. However, *in vitro*, in the presence of large amounts of glucose-1-PO_4 and a glycogen primer, the reaction can be reversed, and the newly synthesized polysaccharide can be demonstrated by iodine staining; the density of the staining reaction is thought possibly to be related to the chain length[9].

Fresh coverslip smears of bone marrow were air-dried at 4° C for 2–3 h. After the smears had been fixed in 70 per cent acetone for 30 sec, they were incubated in the substrate solution prepared according to Quaglino and Hayhoe[7]. Positive controls were obtained by using previously tested specimens which had been stored at −10° C for not longer than 36 h; negative controls included unincubated smears. Occasionally a few megakaryocytes in unincubated smears showed a light-brown cytoplasmic staining reaction consistent with areas of pre-formed glycogen, but no dark blue or blue-black staining reactions were noted in any negative controls.

Staining reaction and distribution in megakaryocytes (Figs. 1–3). In each case a minimum of 50 consecutive magakaryocytes were evaluated for intensity of staining reaction. Enzymatic activity was semi-quantitated according to the following scheme:

Value	Staining activity
0	Absent or faint.
1	Distinct diffuse or distinct fine granularity.
2	Distinct fine granularity plus a few coarse granules.
3	Many coarse granules.

Bone marrow from five patients who were evaluated for non-neoplastic and non-thrombocytopenic haematologic dyscrasias had an average megakaryocytic phosphorylase score (MPS) of 85 with a range of 74–99. Three patients with chronic ITP before splenectomy had an average score of 141 with a range of 104–173. One patient with a reactive thrombocytosis following traumatic fracture and haemorrhage had an MPS of 204.

The intracellular site of phosphorylase activity, as determined by periodic acid–Schiff reaction after diastase digestion, closely parallels that of pre-formed glycogen. Quaglino and Hayhoe[7] suggest the similar intracellular distribution of pre-formed glycogen and phosphorylase activity may be related to the presence of pre-formed glycogen acting as a built-in primer. The higher average phosphorylase scores for patients with ITP, therefore, correspond to the increased number of coarse PAS-

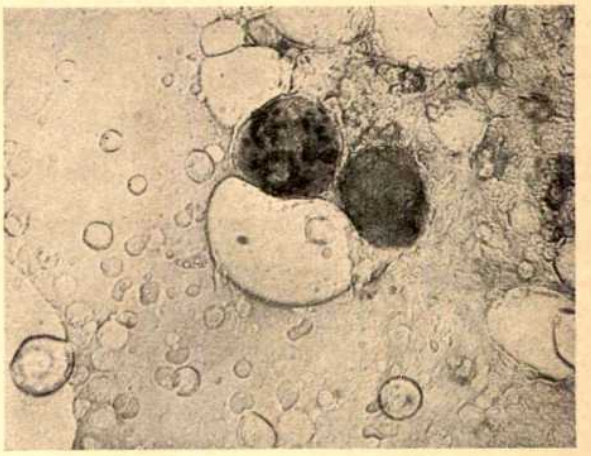

Fig. 1. Phosphorylase activity in megakaryocytes. Two megakaryocytes from a patient with chronic ITP before splenectomy. The more intensely staining cell is scored as 3; the less intensely staining cell is scored as 1

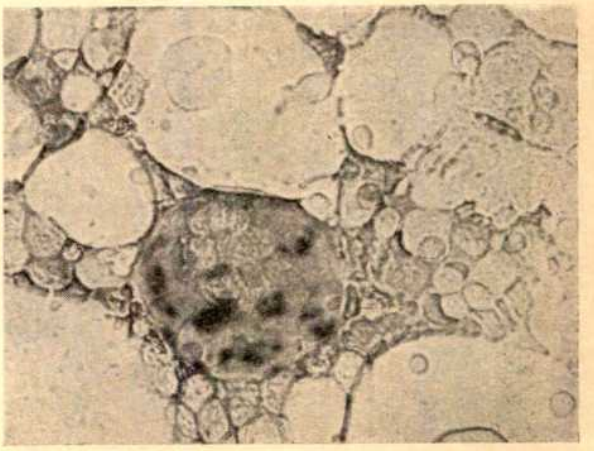

Fig. 2. Pre-splenectomy. Phosphorylase activity in a megakaryocyte. A few coarse granules give this cell an MPS of 2

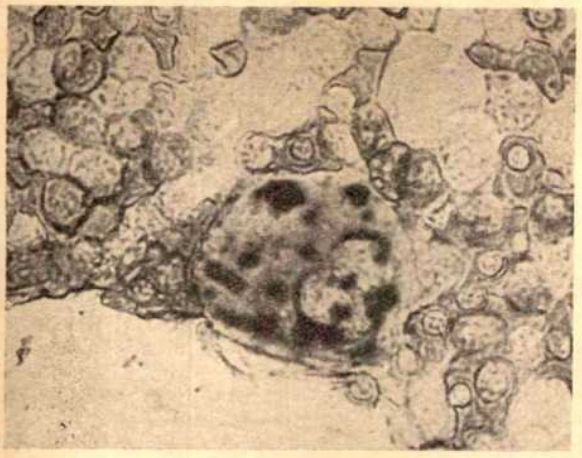

Fig. 3. Pre-splenectomy. Phosphorylase activity in a megakaryocyte. Many coarse granules rate an MPS of 3

positive granules. The high MPS in the patient with reactive thrombocytosis after traumatic haemorrhage is consistent with increased megakaryocytic glycogen as noted by Daniell[6] in humans after acute blood loss and as found by Etcheverry and Grignaschi[3] in experimental animals.

These preliminary investigations suggest there may be considerable variation in megakaryocytic phosphorylase activity and also that the enzymatic activity roughly parallels the amount of intracellular glycogen. There is, however, no indication by this *in vitro* technique that there is a phosphorylase deficiency in chronic ITP before splenectomy. The possibility of the absence of or diminished concentration of a primer or initiating factor necessary for phosphorylytic cleavage *in vivo* remains to be examined.

I wish to acknowledge the services of the Medical Photographic Laboratory, Letterman Army Hospital, San Francisco.

Action of Riley's Enzyme-elevating Virus on Tumour-bearing Mice

RILEY virus (RV) is a passenger agent occurring in most mouse tumours which are subjected to repeated transplanting passages[1–6]. The influence of this virus on tumour-bearing hosts has not yet been clarified, though its stimulating and accelerating effects on tumour-growth have been discussed[3,5]. There is a significant elevation of LDH-values after virus-infection of tumour-bearing mice as compared with tumour-free hosts[1,3,5] (termed 'tumour-virus synergism' by Riley[5]). This phenomenon is of special interest, because the natural occurrence of RV is almost restricted to tumour-bearing mice. Enhanced values of plasma-LDH in tumour hosts[7] might be induced mainly by RV. We have investigated the effects of RV on three different tumours of mice previously free of the agent.

First, mice with spontaneous mammary tumours (Swiss- and *C3H/He J*/Han-lines), collected from older breeding females, were inoculated with about 3,000–4,000 *I.D.* of RV by intraperitoneal injections. Values of plasma-LDH were followed by enzyme determination at 2- or 3-day intervals up to more than 4 weeks. Levels of plasma-LDH increased almost two-fold as compared with tumour-free Swiss mice infected with the same amount of virus. Table 1 shows the development of enzyme elevation, giving the values at six selected days only. Values are representative means for many animals from several repeated experiments.

The second species of tumour-host developed polyoma-induced carcinomata following infection of new-born Swiss-*NMRI*/Han mice with *SE*-polyoma virus. These tumour-animals showed a similar reaction of plasma LDH after primary infection with RV to that of mice with spontaneous mammary tumours. We have an impression that tumour weight might be a substantial factor influencing LDH-increase in some animals; but it was not possible to determine a relation between enzyme elevation and tumour mass.

The average values of plasma LDH in both kinds of tumour cover both very low and extremely high responses of plasma enzyme to virus inoculation. The latter enhancement was comparable with the previously reported synergistic action[3,5], but in our experiments the single animals with high, short peaks of LDH died rapidly.

Table 1. PLASMA LDH IN THREE TUMOUR SPECIES AFTER INFECTION WITH RILEY'S LDH-ELEVATING VIRUS

Days after RV infection	0	4	7	10	14	21	28
Spontaneous mammary tumours	58	155	263	233	185	202	145
Polyoma virus-induced tumours	89	217	239	233	222	233	171
Transplanted tumours (carcinoma 284)	39	224	208	261	325	364	396
Tumour-free controls	31	148	150	149	154	148	150

Numbers give enzyme activities in Buecher units per ml. plasma. Values are means from forty animals of at least six repeated experiments in each of the three species of tumours and controls.

After these findings of a moderate virus-tumour synergism in hosts with primary tumours, a transplanted tumour was used to investigate the action of RV. The tumour was developed in this laboratory by transplantation of a spontaneous mammary carcinoma of an inbred *C3H/HeJ* Han mouse to inbred *C3H*-hosts. The tumour is now in its fourteenth passage of transplantation and is referred to as carcinoma 284; animals of the sixth to eighth passages were used in these experiments.

About 14 days after RV-infection of the transplanted carcinoma 284 the results differed as follows: an almost tenfold increase of plasma-LDH resulted 14–28 days after virus inoculation, whereas mice with primary tumours showed an approximately six- to seven-fold increase, compared with a five-fold increase in the controls, during this period of observation. Therefore, the synergistic action of RV with tumour-bearing hosts was demonstrated most clearly in animals bearing the transplanted carcinoma 284. This result seems to be of interest, because host mice with the various transplantation tumours, usually infected with RV, show very enhanced plasma-LDH as compared to virus-infected tumour-free controls.

Titres of RV in transplanted carcinoma 284 were not elevated as compared to spontaneous or polyoma-induced tumours, though we found that the titre was 100–1,000 times higher in the tumours than in the organs of the same host. The synergistic effect in tumour animals cannot, therefore, be explained by an enhanced virus propagation. In accordance with the impaired clearance of LDH after infections with RV (refs. 4, 8), it might be considered that enzyme-discharging cells of the reticulo-endothelial system are blocked by influences of the tumour tissue before virus infection.

Amyloidosis in Mice with a Transplantable Plasma Cell Tumour

Transplantable plasma cell tumours of mice resemble human myelomatosis in the following features: morphology of the tumour cells[1], production of globulins[2], Bence Jones type of proteinuria[3], osteolytic bone lesions[4,5], and myeloma kidney[3,6]. All these features, however, are not present simultaneously in any one strain of neoplasm. Since systemic amyloidosis has been reported in 14 per cent of cases of human myelomatosis[7], the presence of amyloid in mouse myelomatosis was investigated.

The tumour chosen for study was the *ADJ/PC5* which arose in a *BALB/c* mouse following an intraperitoneal injection of incomplete Freund's adjuvant and heat-killed staphylococci[8]. The 61st generation of this tumour was transplanted subcutaneously by the trochar technique into the right flank of ten 8-week-old female *BALB/c* mice using 2-mm fragments of a 14-day donor tumour. A further series of ten mice served as controls. The animals were maintained on a diet of rat cake, supplemented with biscuits, wheat and maize. They were killed by cervical fracture on the 24th experimental day.

The serum of the tumour-bearing animals was characterized on paper electrophoresis by a slow-moving narrow band of γ-globulin, which on immunoelectrophoresis was a γ G globulin, and on ultracentrifugal analysis had a sedimentation coefficient of 6·4*S* ($S_{20}W$). Animals with large tumours showed proteinuria, but Bence Jones protein was not detected.

Representative pieces of tissue were taken from the tumour, liver, spleen, kidney, heart, tongue and femur of each mouse. They were fixed in 4 per cent formaldehyde saline, and the bones were decalcified in buffered formic acid. The tissues were processed routinely and stained with haematoxylin and eosin, methyl violet[9], congo red[10], thioflavine-*T* (ref. 11), periodic acid–Schiff (PAS)[12], van Gieson, silver[13] and methyl green-pyronin[14].

The tumour was a well-defined lobulated fleshy mass confined to the subcutaneous tissue. Macroscopically no metastases were found at post-mortem. Of the visceral organs, only the spleen showed definite enlargement. Microscopical examination of the tumour showed a variable appearance (Fig. 1). There were sheets of well-differentiated plasma cells at some sites, with frankly necrotic areas at others. A large part of the tumour, however, consisted of lobulated masses of pleomorphic cells. These cells were large, round or oval in shape with basophilic cytoplasm, and showed intense pyroninophilia. The nuclei were large and irregular, and there were numerous bizarre mitotic figures. Collagen fibres were sparse, but a well-defined reticulin network outlined the lobulated structure of the neoplasm. There was no histological evidence of tumour metastases, and the bone marrow was free of tumour.

Table 1. Distribution of Amyloid in *BALB/c* Mice carrying the *ADJ/PC5* Tumour

Tumour mouse No.	Amyloid present in the following organs								
	Tumour	Liver	Glomerulus	Tubules	Myeloma casts	Spleen	Heart	Tongue	Bone
(1)	+	+	+	+	+	+	–	–	–
(2)	+	+	–	+	–	–	–	–	–
(3)	+	+	+	+	–	–	–	–	–
(4)	+	+	+	–	+	–	+	–	–
(5)	–	–	–	–	–	–	–	–	–
(6)	–	–	–	–	–	–	–	–	–
(7)	+	+	+	–	+	–	–	–	–
(8)	+	+	+	–	–	+	–	–	–
(9)	+	+	+	–	+	–	–	–	–
(10)	+	+	+	+	+	–			–

Microscopic foci of amyloid were found in eight of the ten tumour-bearing animals, but in none of the control mice. Amyloid was identified by the intense pale green fluorescence with thioflavine-*T*, a strong PAS-positive reaction, and a khaki colour imparted by the van Gieson stain. Congo red binding was weak; birefringence, dichroism and methyl violet metachromasia were absent. Amyloid fibrils were demonstrated with the electron microscope[15]. The thioflavine-*T* reaction was used to find the distribution of amyloid (Table 1); false positive reactions of certain structures were strictly excluded[16], and the lack of autofluorescence was a further requirement[17].

The tumour and liver were involved in eight mice. In the tumour, amyloid was usually found in the vascular sinusoids (Fig. 2). In the liver amyloid was present in the sinusoids and the portal and centrilobular veins (Fig. 3). Renal involvement was noted in the glomeruli of seven mice, and in the tubules of four (Fig. 4), while myeloma casts were found in six mice. Myeloma casts showed identical reactions to those of amyloid (Fig. 5)

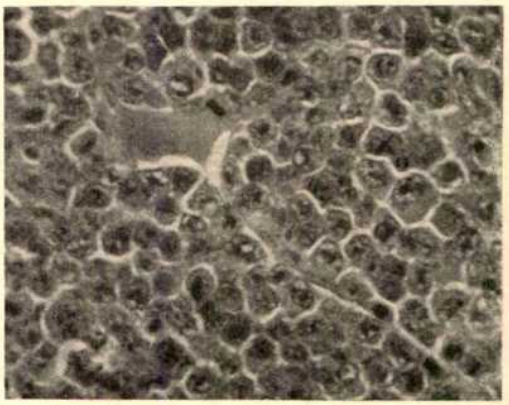

Fig. 1. Plasma cell neoplasm *ADJ/PC5*, showing cellular pleomorphism, and a small focus of amyloid (stained with haematoxylin eosin, × *c.* 365)

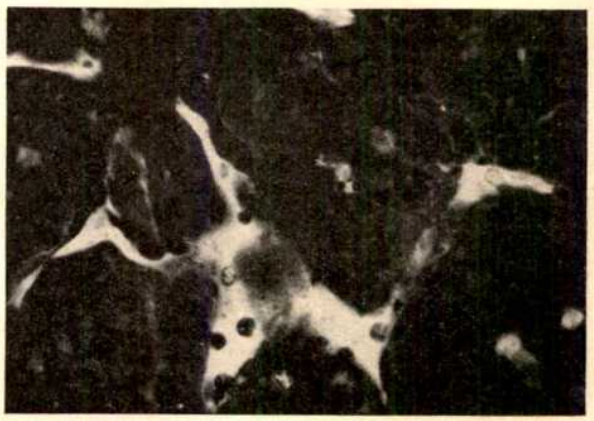

Fig. 2. Fluorescent microphotograph showing amyloid among cells of the plasma cell neoplasm (stained with thioflavine-*T*, × *c.* 365)

and they are therefore comparable with myeloma casts in man[18,19]. Small perifollicular foci of amyloid were observed in the spleens of two mice and the heart was involved in one animal.

Atypically staining amyloid occurs in a proportion of cases of human myelomatosis and was also found in mice bearing the *ADJ/PC5* tumour. The distribution was not that of the classical 'primary' amyloidosis usually found in human myeloma. However, as Symmers[20] has shown, there is considerable overlap in the distribution of amyloid between the primary and secondary varieties.

It appears that the plasma cell tumour was responsible for amyloid formation and the observations made are consistent with the cellular theory of Teilum[21]. Osserman *et al.*[22] have recently presented evidence to show that plasma cell neoplasia or dyscrasia may be found in all cases of human amyloidosis. The presence of amyloid in mice bearing the plasma cell tumour lends support to these views.

Micro-architecture of Skin and its Behaviour under Stress

IT has recently been shown that the mechanical characteristics of human skin are peculiar both *in vivo*[1] and *in vitro*[2] and do not correspond exactly with those of any known isotropic material. It was found that the increase in the length of portions of skin under increasing load was relatively large at first, but a point was reached when further loading produced little increase in length up to the point at which the specimen failed completely. Moreover, it was suggested that the behaviour of skin under mechanical stress is related to the anatomical arrangement of the collagen and elastic fibres in the dermis which our preliminary histological investigations tend to confirm. We have found, in addition, certain unexpected changes particularly in the dermal collagen after stress[3].

The collagen within the dermis can be divided into three layers according to its histological architecture; 1, a narrow sub-epidermal zone of loosely arranged fine fibres; 2, a wider mid zone of more compact coarse fibres; 3, a deep zone of variable thickness which consists of coarse collagen fibres more loosely arranged than in the mid zone. In all three layers the collagen fibres are normally laid down in a three-dimensional interlacing network.

For our histological investigations we used mainly human skin from the abdominal wall obtained at necropsy, because of its greater availability, and a limited amount of work has been done on skin taken from various sites in live patients during plastic operations. Normally two portions of skin were obtained, one taken horizontally across the abdomen and the other vertically. Specimens were investigated following varying degrees of stress up to and including failure, and after having been stretched over varying periods of time. Some specimens were fixed while still in the stretched condition and others were allowed to relax before fixation.

When skin is stretched the collagen fibres of the dermis lose their random three-dimensional arrangement and become orientated along the line of stress, that is, parallel with the surface. At low loads only a few fibres are re-orientated, but with increasing strain progressively more fibres become altered until all the collagen fibres in the mid zone lie parallel to the surface. Eventually transverse fracture lines appear in the fibres and these increase until complete disruption of the skin occurs. This orientation of the collagen fibres in the line of stress is obvious no matter in which direction the force is applied. The sub-epidermal and deep zones of the dermis follow the same pattern as the mid zone but lag somewhat behind. It is surprising to find that elastic and reticulin fibres seem to be largely unaffected by stretching; they are merely displaced by and compressed between the orientated bundles of collagen.

Certain unexpected staining differences were observed after stretching. With Mallory's trichrome stain[4] the normal collagen stains blue. In contrast, stressed collagen fibres stain red (fuchsinophilia) and thus resemble smooth muscle. This alteration is completely reproducible when stressed and control specimens are compared in successive sections from a single block of stressed skin, and whether the staining technique is manual or entirely mechanical in an automatic staining machine. We have obtained the same results with modifications of Mallory's method, for example Masson[5], picromallory[6], Foot[7] and the Falg method[8]. Lendrum's Martius-Scarlet-Blue[6] method demonstrates the change particularly well.

The alterations in orientation and staining appear to be closely linked, but usually the fibres become orientated before the change in staining properties occurs. The greater the stress the greater the number of collagen fibres which become fuchsinophil.

If the skin is stretched and allowed to relax before fixation it is noticeable that after small degrees of stretching the collagen fibres return to their three-dimensional interlacing pattern but retain their affinity for acid fuchsin. At greater stress levels the fibres remain orientated in the line of stress, but show a wavy, concertina pattern after relaxation in addition to retaining fuchsinophilia. Fracture lines only occur when stretching is great enough to produce changes which are irreversible on relaxation.

It is not yet clear what alteration is responsible for the change in staining reaction, but it is probably connected with the unique micro-structure of collagen. The collagen fibril consists of long-chain protein molecules arranged in regular parallel straight rows within a matrix of acid mucopolysaccharides (Curran and Clark[9]). It may be that in the normal collagen fibril only the mucopolysaccharide is stained and that this produces the blue reaction by any of the trichrome methods. On the other hand, in the stressed fibril the mucopolysaccharide is disrupted allowing access of the dye to the protocollagen which is fuchsinophil. In support of this possibility some of our material shows that these fuchsinophil fibres are surrounded by a faintly discernible blue envelope. This, however, fails to explain why the blue reaction of the mucopolysaccharide should largely disappear. Further, special stains for acid mucopolysaccharides, for example, thionin, toluidine blue and methylene blue extinction, do not disclose any difference between normal and stressed collagen.

Whatever the cause, we find that the tinctorial changes in stressed collagen closely resemble those described as 'fibrinoid degeneration of collagen' in some of the collagen diseases, for instance, scleroderma and the rheumatoid nodule. It is entirely different from the fibrinoid exudate seen in the walls of blood vessels or the renal glomeruli in cases of malignant hypertension, in polyarteritis nodosa and diabetic vasculosis. We believe that the so-called fibrinoid necrosis of collagen, whatever the cause, has no relation to fibrin, and we suggest that it would be more rationally termed 'stressed collagen' using the term stress in the wide sense of damage caused by any agency whether physical, chemical or biological.

Is Hodgkin's Disease a Syndrome of Hypothymism?

There has been much discussion recently, based on both X-ray and autopsy evidence, about the role of the thymus in the development of Hodgkin's disease[1,2]. Quite recently, Hoffbrand[3] failed to show auto-immune phenomena or thymus involvement in Hodgkin's disease.

On the other hand, the immunology of Hodgkin's disease strongly indicates a profound impairment of the lymphoid system. In recent years, the presence of dissociation of antibody formation and of immunological reactions of the delayed type has been clearly established in Hodgkin's disease.

Even in the early stages of Hodgkin's disease there is a marked suppression of immunological responses of the delayed type to different antigens, tuberculin, mumps virus, *Candida albicans*, *Trichophyton gypseum*, diphtheria toxoid, streptokinase-streptodornase and dinitrochlorobenzene. The response to homografts of skin and bone marrow is similarly affected. At the same time, antibody formation to a large number of antigens remains unimpaired (for a review of this topic see refs. 4–6). Similarities between malignant lymphomas and graft-versus-host reactions were noted by Kaplan and Smithers[7], while Green *et al.*[8] questioned whether patients with Hodgkin's disease were lymphoid chimeras. Aisenberg[5] claims that, in contrast to the immunological status in Hodgkin's disease, both immunological responses of the delayed type and antibody formation are absent in graft-versus-host reactions. Aisenberg made the same observation when comparing the status of neonatally thymectomized animals and the status in Hodgkin's disease: "Thus it seems that a number of clinical features of Hodgkin's disease including the immunological defect cannot be adequately explained by incriminating a loss of thymic function. However, in the terminal stage of disease many features are similar to the post-thymectomy state, and it appears possible that the two could represent the same end stage of different etiologic processes".

New data on the histopathology and immunology of the post-neonatal thymectomy state raise the question whether Hodgkin's disease can be considered as a syndrome of hypothymism. Earlier, it was established that, in neonatally thymectomized animals, both antibody production and immunological responses of the delayed type were suppressed[9,10]. This was in accord with the well-known depletion of small lymphocytes in lymphoid organs[9–11] combined with the proliferation of reticular and plasma cells[11,12]. In contrast to these initial data, Svet-Moldavsky *et al.*[11] showed that neonatally thymectomized mice retain the capacity to produce antibody. For some antigens (*Vi*-typhoid antigen, live influenza virus) antibodies are produced immediately after the primary immunization, for others (sheep erythrocytes, *O*-typhoid

antigen) only after re-immunization[11,12]. This is very similar to the production of antibodies to tetanus toxoid in patients with Hodgkin's disease only after re-immunization which was noted by Barr and Fairley[13].

In neonatally thymectomized mice in which immunological reactivity had been recovered by re-immunization, some lymph nodes and the spleen recover the normal histological pattern, while other lymph nodes retain scantiness of lymphocytes, absence of germinal centres, and hyperplasia of reticular and plasma cells[11,12]. Quite recently, it was demonstrated in this laboratory[12] that neonatally thymectomized mice can also produce antibody to sheep erythrocytes after the primary immunization. In this case, antibody production begins later but persists longer than in normal animals. Antibody can reach even higher titres than normally. Such antibody production is explained by an enhanced proliferation of immature cells of the plasma series and a slowing down of their maturation.

All the foregoing evidence indicates that, in neonatally thymectomized animals, there occurs not a general loss of the immune response, but its clear dissociation, which is identical in detail with the immunological defect in Hodgkin's disease. The histopathological pattern in neonatally thymectomized mice subjected to the effects of antigens, with sharp variations in the structure of different lymph nodes in one and the same animal, is strikingly similar to that seen in Hodgkin's disease.

We suggest that the pathogenesis of Hodgkin's disease is based on a definite hypothymic-hypolymphocytic syndrome characterized by depletion (and possibly a quantitative insufficiency) of the lymphocytes of lymphoid organs, lymphopenia in the peripheral blood, enhanced proliferation of reticular and immature plasma cells and loss of immunological responses of the delayed type with retained capacity for antibody production. Proliferation of cells of the plasma series may result in hypergammaglobulinaemia which cannot, so far, be explained.

Of course, individual features of the syndrome of hypothymism may be manifested to a greater or lesser extent. The pattern of the syndrome may change considerably, due, for example, to secondary chronic infections or to the involvement of other systems. Prolonged antigenic stimulation in the syndrome of hypothymism may result in the formation of cells of the Sternberg–Berezovsky type.

This concept of the syndrome of hypothymism is not equivalent to hypofunction or lack of function of the thymus. This syndrome may depend on hypofunction of the thymus while at the same time developing from a blocking of the transmission of hormonal or other thymus effects to the effector systems of different levels. Indeed, the syndrome does not necessarily involve a morphological involvement of the thymus in the process.

Of special importance in this syndrome is the impairment of the reciprocal equilibrium of the system of lymphocytes and cells of the plasma series. I believe that antagonistic interaction of these two cellular systems constitutes one of the fundamental homoeostatic mechanisms of the lymphoid system. Selective impairment of lymphocytes or depletion of lymphocytes for any reason (as a result of X-irradiation, neonatal thymectomy, etc.) results in an enhanced proliferation of reticular cells and cells of the plasma series. This proliferation is a very important element of the hypothymic-hypolymphocytic syndrome and underlies the transformation of Hodgkin's disease into reticulosarcomatosis and the existence of many intermediate forms between these diseases.

All the foregoing strongly suggests that transplantation of the thymus tissue should be undertaken for therapeutic purposes in patients with Hodgkin's disease. Even if such grafting will not completely cure the disease, it should result in a marked improvement of all phenomena associated with the state of hypothymism. The absence of immunological responses of the delayed type in patients with Hodgkin's disease would ensure the durability of the thymus homograft.

BIOLOGY

Photographic Method of Recording the Activity of Small Animals using Repetitive Electronic Flash

REPETITIVE or strobed electronic flash has been commonly used in techniques for the analysis of animal locomotion. Some of the methods involved several flashes on to a single photograph, notably in connexion with work on the flight of birds and bats. Dryl[1,2] has described a 'photomacrographic' method for recording the activity of mobile protozoans. This utilized a time exposure to a continuous source of light illuminating the animals against a dark background. His method was developed from similar 'photomicrographic' techniques for activity recording used by other workers[3–6].

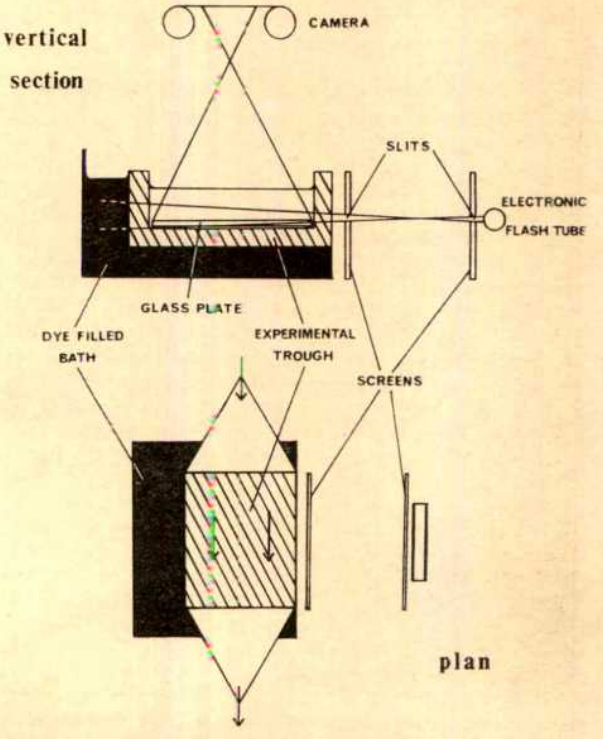

Fig. 1. Diagram of the activity recorder. The arrows in the plan of the apparatus denote the direction of water flow through the trough, and the hatched area the recording field

The apparatus described here (Fig. 1) was designed for recording the activity of small aquatic animals in a shallow trough of water. This measured 8·1 × 10·7 cm and was 2 cm deep. Trail records of the animals appeared as series of discrete images or as a continuous track. This depended on the flashing rate of an electronic flash system, and on the speed of movement of the animals. They were allowed to move freely on glass plates lying on the bottom of the trough in a horizontally uniform flow of water. The brief flashes (about 1 msec) illuminated the animal so that it appeared as a linear series of images of reflected light against a dark background. This was achieved by directing the flashes through two narrow horizontal slits. The light emerged as nearly parallel flat beams across the bottom of the trough. It was important to minimize stray scattered light which reduced the efficiency of the dark background. On long exposures, this tended to fog the single frame of photographic film on which the record was made. The film was exposed in a conventional 35 mm camera with the aperture set at *f*4 and the shutter left open. It was mounted on a light-proof box over the trough, and focused on the animal. Micro-copying film (Kodak 'Microfile'), which is very slow (A.S.A. 2), fine grained and contrasty, was found to be most suitable. The trough was immersed in a bath of red dye which served to increase the efficiency of the dark background by absorbing some of the stray scattered light. Transparent 'Perspex' sheet was used to construct the trough and parts of the rest of the apparatus. The light source and the screens were shielded in so that the light only passed through the narrow slits. Holes were provided for ventilation to prevent overheating on long runs of flashing.

Under these conditions, records of the relatively slow-moving activity of certain small lamellibranchs (Fig. 2) were made. These records were made over several hours, usually at a flashing rate of once every 10 sec, in the course of an investigation[7] of the behaviour involved in the maintenance of their 'commensal' associations. An ordinary portable single flash unit (Mecablitz 108) was used and a Palmer mechanical time switch was included in the flash tube triggering circuit so that it would fire repetitively. This allowed a range of flashing rates (limited by the re-cycling period of the flash unit) from once every 5 sec.

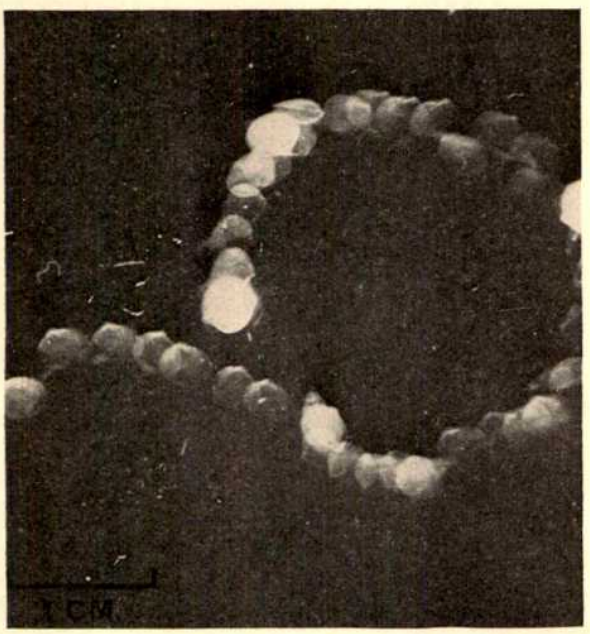

Fig. 2. Part of the photographic record made by a single specimen of the bivalve *Montacuta substriata* walking across the bottom of the trough. The orientation of the animal can be discerned from the individual image components of the track. The more saturated images indicate where the animal was stationary for a period

A more reliable electronic method for triggering a flash tube has since been used. This was constructed by the Benthos Company of North Falmouth, Massachusetts, U.S.A. It incorporated a silicon-controlled rectifier as an electronic switch for the discharge of a capacitor. The latter triggered the flash tube (G.E. *FT*-30) which yielded about 10 w sec/flash. This was found to be quite adequate for my recording conditions. Adjustment of a resistor-capacitor system allowed the flashing rate to be varied over a wide range.

The size of the recording field and the size and the nature of the activity of the experimental animal would determine the exact nature of the components of the electronic flash system in other applications. It should be as simple to construct and use this recording method for terrestrial as with aquatic organisms.

Intraretinal Discrimination of Horizontal and Vertical Planes of Polarized Light by Octopus

Since the early investigations of von Frisch[1,2], it has been known that some arthropods have an ability to discriminate different planes of polarized light. Recent investigations, using intracellular microelectrodes[3–5], have disclosed that the receptor cells themselves are the analyser for polarized light, although there still remains disagreement as to the existence of the intraocular analyser[6].

In a behavioural study, Moody and Parriss[7] found that the octopus could differentiate planes of polarized light at right angles. Based on this observation and also on the structural similarity in the rhabdomeres between the insect and cephalopod, these authors have proposed a hypothesis that the mechanism for analysing the plane of polarization lies in the octopus retina. In the present investigation of the octopus electroretinogram (ERG), it was found that the octopus retina can indeed discriminate between the horizontal and vertical planes of polarization, and the horizontal–vertical arrangement of the rhabdomere tubules was considered to be the structure responsible for the discrimination.

The animals used were *Octopus vulgaris*. The cornea, lens and vitreous fluid were removed, and the retina was flattened, sclera downwards, on a large plate of silver–silver chloride which served as the indifferent electrode. An *in situ* orientation of the retina was maintained so that the horizontal line of the retina (which corresponds to the direction of the slit pupil) was parallel to the front edge of the experimental table. The light source was a glow modulator tube (Sylvania *R*1131*C*) which was activated by an electronic pulse generator. The light source, condenser lens and 'Polaroid' filter were arranged so that a parallel beam of polarized light was projected perpendicularly to the retina. By this arrangement of the optical system and retina, all possible factors that might cause intensity variation with rotation of 'Polaroid', such as reflexion, refraction, scattering and absorption in the optical pathway, could be minimized. The relative angle between a plane of polarization and the horizontal line of the retina was varied by rotating the 'Polaroid' which was interposed between the retina and lens.

On illumination of the retina by polarized light, a sustained negative response (ERG) was recorded from glass

capillary microelectrodes placed on the retinal surface. The ERG had the characteristics already described elsewhere[8]. In a number of cases the ERG was found to fluctuate in amplitude periodically as the 'Polaroid' was rotated around the optical axis, having two maxima and two minima in one complete turn. But the fluctuation of the ERG must be an experimental error, because it could be minimized by complete flattening of the retinal surface.

The technique adopted was selective adaptation. The retina was first illuminated intermittently by a flash of light (100 msec in duration, about once every 5 sec) while the 'Polaroid' was rotated during a dark period (control run). When fluctuation of the ERG was seen in the control run, the recording site was moved to another retinal area and the control run was repeated until no variation of ERG was found. But this procedure was rarely needed, whenever the retinal surface was held flat. Then a steady light of 20–60 sec in duration was delivered while the 'Polaroid' was fixed at a certain position (selective adaptation). Following light adaptation, the same procedure was repeated as in the course of control run (test run). The result is shown in Fig. 1*A*. For adapting light at 0°, with the plane of polarization perpendicular to the horizontal axis of the retina, the minimal response to test lights appeared at 0° and 180°, and the maximum at 90° and 270° (Fig. 1*A*, top). When the plane of polarization of adapting light was at 90°, the minimum appeared at 90° and 270°, and the maximum at 0° and 180° in the test run (Fig. 1*A*, middle). No such effect of selective adaptation was observed when the e-vector of adapting light was at 45° (Fig. 1*A*, bottom) or at 135°.

The similar effect of selective adaptation could also be demonstrated by a different method. The retina was illuminated repetitively by a flash of polarized light at 0°, and, when the ERG was reduced in amplitude due to light adaptation, the 'Polaroid' was rotated from 0° to 90°. Then the same number of flashes were given at 90°, and the 'Polaroid' was again rotated back to 0°. This procedure was repeated several times. Enhancement of ERG was readily seen immediately after the plane of polarization was rotated either from 0° to 90° or from 90° to 0° (Fig. 1*B*, top and bottom). However, when the e-vector was rotated from 45° to 135° or vice versa, no such temporary increment of response was seen (Fig. 1*B*, middle). From these observations, it is obvious that the octopus retina differentiates the horizontal and vertical planes of polarization, but not oblique planes of 45° and 135°.

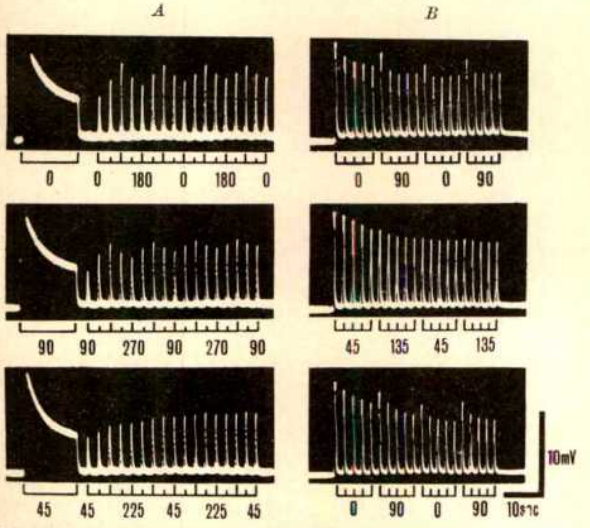

Fig. 1. Oscilloscope tracing of octopus ERG. DC recording. *A*, Retina was first light-adapted at 0° (vertical) for top, 90° (horizontal) for middle, and 45° (oblique) for bottom record. The 'Polaroid' was then rotated at 45° interval. *B*, Five flashes in same plane of polarization, then the 'Polaroid' was rotated by 90°, and the same procedure was repeated. Experiment was carried out from top to bottom in both *A* and *B*. Numerals under each record indicate position of 'Polaroid' in degree

If the e-vector of adapting light is deviated from the standard direction (horizontal line of the retina) by $\delta(<45°)$, then the question arises whether the minimum responses would appear at δ (and maximum at $\delta + 90°$), or the minimum would appear still at 0° (and maximum at 90°). The next experiment answered this question. The retina was first light-adapted at 30° or 330° (that is, ±30° deviated from 0°), then the test run followed. The result was the same as in the case of selective adaptation at 0°, the minimum appearing at 0° and maximum at 90° for adapting light at 0° ± 30°. For adapting light at 90° ± 30°, the minimum appeared at 90° and maximum at 0°. Thus, the position at which the minimum and maximum appeared in the test run was independent of the direction of the e-vector of adapting light, when the e-vector was deviated from the standard direction of the retina by less than 45°. If the e-vector of adapting light was deviated equally from the two standard directions (±45° from horizontal line), no minimum and maximum appeared in the test run.

The same experiment was repeated at various regions in the retina. The results were the same at all retinal areas, showing no regional differences.

These results suggest that in the octopus retina there are two analysers, one lying horizontally and the other vertically, and that they are selectively stimulated and consequently light-adapted by either horizontal or vertical components of incident light. It follows that the octopus retina can discriminate the horizontal and vertical planes of polarization, but not the oblique planes of 45° and 135°. Since all factors which cause intensity variation by reflexion or scattering with rotation of the 'Polaroid' had been eliminated in the stimulating system and dioptric apparatus of the eye, the analysing mechanism must lie in the retina. In the octopus retina the rhabdomes are arranged in a rectangular array, lying in the horizontal and vertical directions[9], and in these directions closely packed fine tubules, rhabdomeres, leave the receptor cell surface perpendicularly[7]. Thus it may be concluded that the horizontal–vertical arrangement of rhabdomeres could provide the morphological basis for the discrimination of plane of polarization in the octopus.

Additional details of these and related experiments will be published separately[10].

We thank Prof. K. Motokawa for his support and suggestions and the staff of the Marine Fisheries Laboratory for collecting and maintaining octopuses.

Circadian Rhythms in the Feeding Behaviour of *CBA* Mice

MANY vital processes have marked diurnal rhythms in natural circumstances; and in the laboratory, even under the most constant conditions possible, they still show cycles with a period approximating 24 h ('circadian rhythms'[1]). From his observations on rats, however, Siegel[2] concludes that the diurnal rhythm in the feeding behaviour of this species disappears in 6–10 days in animals

kept under continuous light. (The same conclusion was previously reached by Baker[3], but in our opinion on the basis of an inadequate analysis of the feeding behaviour of his animals.) This conclusion was justly criticized by Aschoff[4]; Siegel's pooling of data for a group of subjects may have obscured the existence of non-synchronous cycles in the different individuals. Therefore, as a preliminary to other investigations on the physiological mechanisms of feeding behaviour in mammals, we have re-investigated this point.

Our subjects were *CBA* mice, kept for two generations under continuous light and constant temperature (24° C). The data reported here refer to 20 males, 5 months old at the start of the experiment, kept individually in 22 × 22 × 15 cm cages, where they could hear but not see one another. Water and dry laboratory food were given *ad libitum*. Automatic records[5] were taken of the time patterns of gnawing at this food in each individual over 24-h periods.

Typically, the mouse gnaws until it has loosened a small piece of food. Then it withdraws from the food to ingest this 'bite'. In all cases there are marked fluctuations in the frequency of bites in the course of the 24-h observation. To analyse these fluctuations, we divided each observation into six 4-h periods, and counted the number of bites in each of these. If we term the period with the greatest number of bites the 'peak period', a record can obtain 0–5 pre-peak periods and 5–0 post-peak periods, depending on whether the peak fell early or late in the observation. For each period of a record the number of bites in that period was expressed as a percentage of that in the peak period of that record. Fig. 1 gives the median of the percentage for each period (total of seventy-five observations on twenty individuals). The distribution-free confidence intervals for each median are shown with confidence coefficients as close to 0·950 as possible. The actual coefficients are shown at the top of Fig. 1 (see Kendall and Stuart[6]). Fig. 1 strongly suggests that a rhythm is present. Although the precise periodicity underlying the original data cannot be derived from this figure, the form of the curve suggests a rhythm of about 24 h, that is, a circadian rhythm.

The statistical significance of this rhythm was tested as follows. The null hypothesis, that is, that our observations could be considered as a purely random series, was tested against the alternative hypothesis that there is an underlying periodicity of approximately 24 h by calculating the total number of ways in which six numbers can be so arranged as to give a result in agreement with such an alternative hypothesis. This number, when divided by the total number of different ways in which six numbers can be arranged (6! = 720), yields the probability under the null hypothesis that a random batch of six numbers in random order agrees with the alternative hypothesis. The number of times one can have agreement in N such

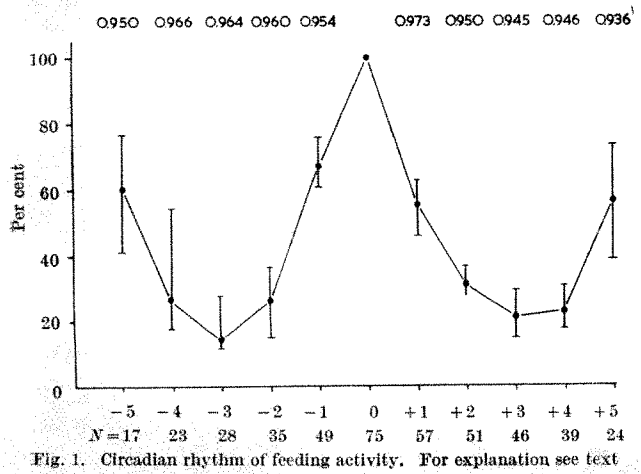

Fig. 1. Circadian rhythm of feeding activity. For explanation see text

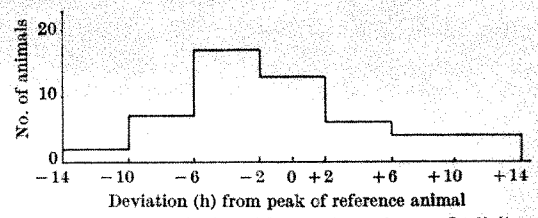

Fig. 2. Frequency distribution of degree of asynchrony of activity peaks (in relation to an arbitrarily chosen reference, individual); compilation of data for the entire period of observations

batches is, then, a binomial variable. The test consists of rejecting the null hypothesis if the number of times agreement has been found is greater than x, where the probability of obtaining x agreements or more under the null hypothesis is less than or equal to the level of significance chosen. In our data, agreement was present in 48 out of 75 cases ($P \ll 0{\cdot}01$).

We conclude, in contrast to Siegel, that at least in mice kept under continuous light, feeding behaviour retains a marked circadian rhythm. It may be added that our data on rats kept under continuous light for two generations also indicate such a rhythm[7].

We have analysed our data in the way just described, for two reasons. First, although there was some indication of inter-individual synchronization, the peak periods of different individuals on the same day often lay far apart (Fig. 2). Secondly, we have not observed any individual over a prolonged uninterrupted series of days; however, in a number of cases the same individual was observed twice on consecutive days or with an interval of only 1, 2 or 3 days. The average period length, estimated from these data, is 25·3 h (average over 97 cycles in ten individuals).

Some preliminary results are also available on the feeding patterns of *CBA* mice injected with aurothioglucose (ATG). During the 'dynamic phase', resulting from this treatment, the animals are strongly hyperphagic. Bite frequency is much increased in all periods, but there is still some indication of a peak period in each record. With the rise in body-weight consequent on the hyperphagia, food intake gradually returns to about normal values, and the animals enter the 'static obese phase'. During the latter, the circadian rhythms of the ATG-treated mice appear identical to those of intact controls. These data suggest that the brain lesions induced by ATG do not affect the mechanism underlying the circadian rhythm in our mice.

Finally, the following example illustrates that these persistent circadian rhythms are to be reckoned with in the interpretation of experiments on feeding behaviour. We have measured feeding activity in mice after food deprivation up to 24 h. Our data strongly suggest that bite frequency after a given deprivation depends on whether feeding is resumed in the active or in the inactive phase of the circadian cycle. Since it appears virtually impossible to eradicate these circadian rhythms from feeding behaviour, we now find it preferable to keep our subjects under conditions where at least the cycles of the different individuals are synchronized, that is, where there is a 'natural' alternation of darkness and light.

Aurothioglucose Sensitivity of *CBA* Mice injected at Two Different Times of Day

Some years ago Brecher and Waxler[1] described for the first time obesity in mice resulting from aurothioglucose (ATG) injection. Since then it has been found that ATG can cause lesions in different areas of the brain[2–4]. Among these, the lesions in the ventromedian hypothalamic nuclei are held responsible for the observed obesity. However, it was also found that the most effective ATG doses caused a high mortality[5].

As the susceptibility of animals to certain drugs, toxic substances, etc., is well known to be strongly dependent on their diurnal rhythm[6], we have carried out experiments to see to what extent this is true for ATG. *CBA* mice (males and females) were kept under a day–night rhythm of 12 h light (0700–1900 h) and 12 h darkness (1900–0700 h). The ages of these animals varied from 4 to 6 months, that is, they were all full-grown. Two different ATG doses were used (0·4 mg/g and 0·5 mg/g bodyweight) of a 10 per cent ATG suspension in oil ('Solganal *B* Oleosum', Schering). The mice were divided into two equal groups of comparable composition with respect to age and sex. One group was injected during their inactive phase (1200 h), the other group during their active phase (2000 h). All the animals were deprived of food for 3 h immediately before injection. The animals were weighed daily at 0830 h.

The results are summarized in Table 1.

Table 1

Group	I		II	
Time of injection:	Day	Night	Day	Night
ATG dose	0·4 mg		0·5 mg	
No. of animals	19	19	31	31
Weight *a**	21·9	22·2	27·3	25·1
Weight *b*†	32·7	31·6	36·2	33·9
Died	1	0	22	5

* Mean body-weight (g) before injection.
† Mean body-weight (g) 1 month after injection.

These data show that the ATG injection strongly promotes weight increase, considering the fact that the weight of normal mice of the same age increases by only 1–3 g per month. There is also a striking difference in mortality between the 'day' and 'night' animals of group II. Apparently the animals are much more sensitive to the toxic qualities of ATG at 1200 h than at 2000 h. To a much lesser degree this can be found in group I. One of the 'day' animals died, some were sick for some days after the injection, whereas of the 'night' animals in this group none showed any sign of illness. I never observed illness or mortality in animals injected with a dose of 0·3 mg/g mouse (23 animals). In this latter case weight increase is only slightly greater than normal.

From these data it can be concluded that the susceptibility of mice to the toxic effect of ATG clearly depends on their metabolic state. It may be that this decreased susceptibility is comparable with that described after food deprivation[7]. There are no indications that there is a difference in the resulting obesity of the comparable day and night groups.

It is noteworthy that twelve of the twenty-seven animals that died in group II went through a phase (starting about 24 h after the injection and lasting for some hours) of frantic biting. During these hours the tongue is seriously injured and becomes a swollen bloody mass protruding from the month. These animals then stop eating and drinking and die after some days. Whether this frantic biting is an aggressive or an exaggerated feeding activity cannot yet be decided.

What the precise cause of death of all these animals may be is unknown to me, but I now know that ATG mortality can be decreased considerably by injecting the animals at the beginning of their active phase.

Because ATG plays a part in the treatment of, for example, rheumatism and asthma, the findings reported here may also have a medical significance. It would seem important to examine more systematically the effect of drugs, medicines, radiation treatment, etc., in relation to the natural day–night rhythm of the organism treated.

Haplospora globosa Kjellm. and *Scaphospora speciosa* Kjellm. in Culture

The reproduction and life-cycle of the order Tilopteridales have attracted the interest of phycologists for a long time. Reinke[1] was the first to investigate these problems and, although he was unable to provide any definite evidence, he concluded that the algae in question represent alternating generations of one species, a sporophyte producing non-motile quadrinucleate monospores and an oogamous gametophyte. Reinke's view was adopted by such authorities as Kylin[2,3], Oltmanns[4] and Smith[5], but rejected by Sauvageau[6] and Christensen[7].

Reinke[1], Nienburg[8] and Dammann[9] tried to culture *Haplospora globosa* Kjellm. and *Tilopteris mertensii* (Turn. in Sm.) Kütz. but without great success. In the former species, only germlings from monospores were obtained.

Haplospora globosa is widely distributed on North Atlantic coasts. In the Oslofjord, the *Haplospora* stage as well as the *Scaphospora* stage, originally described as *Scaphospora speciosa* Kjellm., are rather common in spring (Sundene[10]). Specimens of the *Haplospora* stage were collected in May 1964 near the Biological station, Drøbak, in the middle of the fjord, and cultures were established in Erdschreiber at 5° C with daylight. The specimens were fertile, with stalked monosporangia. Monospores were released and some were isolated before settling, while most of the cultures were started from sporelings attached to the bottom of the mother-dishes. The majority of these sub-cultures were contaminated by diatoms, but some

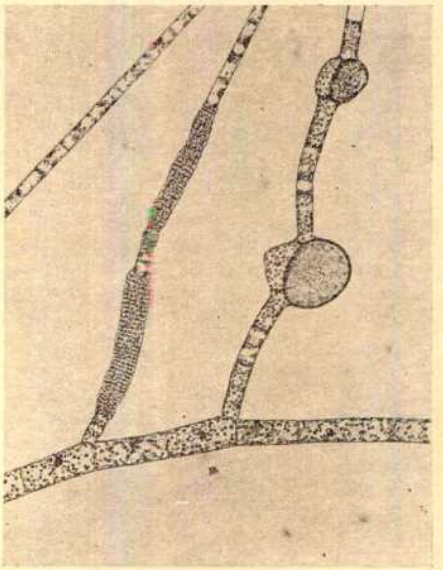

Fig. 1. Branch of the *Scaphospora* stage of *Haplospora globosa* with two antheridia and two oogonia. (× 95)

proved to be unialgal. At first the sporelings grew very slowly and developed during the summer to small, procumbent and zigzag-bent filaments. In the autumn upright shoots sprouted from these filaments. They grew very rapidly, forming tufts 5–10 cm high during the following winter and, early in March, they became fertile, carrying large sessile unilocular as well as plurilocular reproductive organs. The structure of the vegetative thallus and of the reproductive organs accorded with the description of *Scaphospora speciosa* (Fig. 1).

The unilocular reproductive organs of the *Scaphospora* stage contained one large non-motile cell which, after release, settled on the bottom of the dish. From the plurilocular organs a great number of zoids were liberated and a great many of them were observed congregating around the non-motile cells, an indication that they were attracted by the latter.

These observations corroborate Reinke's view that the *Scaphospora* stage represents the gametophyte in the life cycle of *Haplospora globosa* and that the non-motile cells are eggs and the zoids spermatozoids.

Powdery Mildew Fungus on Cucurbits in the Transvaal Province of South Africa

IN her work on South African *Erysiphaceae*, Doidge[1] has provisionally identified the powdery mildew fungus that causes a troublesome disease on Cucurbitaceae throughout the country as *Erysiphe cichoracearum* DC. After two different mildew fungi were found to attack cucurbits in Europe[2], Doidge[3] realized that this identification should be regarded as tentative, but because the perithecial stage of the fungus had not been found in South Africa, more precise identification was considered impossible. Since then, a number of publications have appeared which have pointed out that it is possible to distinguish between the two fungi in question, namely *Erysiphe cichoracearum* DC. ex Merat emend. Salmon and *Sphaerotheca fuliginea* (Schlecht. ex Fries) Poll., on the basis of their conidial characteristics[4–7]. The conidia of the *Sphaerotheca* species contain conspicuous discoid or rod-shaped fibrosin bodies which were first observed and described by Bouwens[8]. They can be clearly seen if the spores are microscopically observed in a 3 per cent aqueous potassium hydroxide solution as recommended by Kable and Ballantyne[7]. In the conidia of *E. cichoracearum*, however, these bodies are lacking. Though both species produce conidia in long chains, the way in which the conidia germinate also differs. The germ tubes of *E. cichoracearum* are all simple and straight, but among those of *S. fuliginea* a number occur that are forked.

Samples of powdery mildew from cucurbits, collected during the past growing season in various parts of the Transvaal Province, all showed long chains of conidia with well-developed fibrosin bodies present in every specimen. Wherever germination of the conidia was found possible, forked germ tubes, like those illustrated by Boerema and Van Kesteren[5], were also observed. The variation of conidial dimensions, 25·2–37·8 × 14·7–23·1μ, in spores of the cucurbit mildew from the Transvaal falls within the range of dimensions given for *S. fuliginea* by Clare[6] (25·0–46·5 × 14·0–25·0μ).

It is therefore concluded that powdery mildew on cucurbits in Transvaal is caused by the fungus *Sphaerotheca fuliginea* (Schlecht. ex Fries) Poll. The disease was observed on cultivars of the following Cucurbitaceae: *Cucumis melo* L., *C. sativus* L., *Cucurbita pepo* L., *C. maxima* Duch. and *C. moschata* Duch. The mildew generally caused a more severe disease on species of *Cucurbita* than on those of *Cucumis*. Considering that even in tobacco-growing areas where *E. cichoracearum* was prevalent, cucurbit mildew samples only showed the presence of *S. fuliginea*, the indications are that in South Africa, like in Australia[4,6], *S. fuliginea* is the only or most prevalent cucurbit powdery mildew.

The Dugong

WHEREAS the manatee of the tropical Atlantic has been the subject of widespread interest in recent years, the related dugong of the Indo-Pacific region has received scant attention. An increasing scarcity over most of the range of the animal has been assumed on the evidence available; for example, few remain in the Red Sea, around Ceylon or Malaysia.

We have recently completed a preliminary survey of the dugongs on the coast of Queensland, in Torres Strait, and elsewhere in the Australasian region. Personal travel and the questioning of innumerable individuals with local knowledge, together with much and continuing correspondence with coastal missions and native reserves, lead on integration to certain encouraging conclusions. Additional correspondence with those having local and personal knowledge will be welcome.

Our conclusion is that in parts of the Australian north-east the dugong is not to be regarded as a rare animal. In places its numbers may even be increasing now, following excessive hunting in the nineteenth century and in the early decades of this century. The world's stock of dugongs is certainly much greater than that of manatees.

On the Australian coasts the hunting of dugongs nowadays is wisely confined to native peoples, whose traditional diet includes these animals. Because of the dugong's acute hearing the process of hunting is not easy: the use of engines in their vicinity is fatal to success, in a way which does not apply in turtle-hunting which is the usual alternative. Because of its difficulty, and because of the progressive movement of the native peoples concerned on to a wage basis and the use of purchased foodstuffs, the hunting pressure on the dugongs would seem to be diminishing in many places.

We believe that under present pressures the dugong stocks on the Australian coasts are secure, although there may be a few places of local excessive killing as certain native groups increase in population. Apart from native hunting, a small number of dugongs are killed inadvertently in fish traps, in official shark-netting programmes for the benefit of bathers, and a few by 'sportsmen'.

We have been able to accumulate, besides extensive personal testimonies, a collection of fresh skeletal and other material, older skulls from kitchen middens and, in

particular, numerous tusks from which it is hoped to determine the relative ages of the animals being killed for food. Further quantities of fresh material and information, it is hoped, will continue to reach us from Queensland and the Northern Territory of Australia.

Our own future investigations will consist of detailed analysis of the evidence and material collected. The opportunity now exists for others to take up the investigation of the dugong's detailed breeding biology by intensive work on freshly killed animals. There are just one or two places, now known to us, where dugongs are taken regularly for food in sufficient numbers and where local help and facilities would be adequate.

MICROBIOLOGY

Leptospires isolated from Frog Kidneys

In the summer of 1964, cases of leptospirosis developed in man as a result of swimming in a farm creek. During epidemiological studies, six leopard frogs (*Rana pipiens*) were collected from these waters. Blood samples were obtained from the frogs. Two pools of kidneys (*A* and *B*) were made from three frogs each. Leptospires were not observed on dark-field microscopy of the kidney suspensions. These were diluted with Stuart's liquid media (1 : 10–1 : 100,000) and 2–3 drops from the dilutions inoculated[1] into semi-solid media: bovine-albumin 'Tween 80' (ref. 2) containing 5-fluorouracil[3] (96 μg/ml.) (Hoffman-LaRoche, Inc., Nutley, New Jersey) and Fletcher's semi-solid media[1]. The inoculated media were incubated at 28°–30° C for 90 days and examined periodically by dark-field microscopy. Leptospires were isolated from pool *B* in albumin 'Tween 80' medium on the twentieth day after inoculation. Observations of the frog isolate by electron microscopy indicated that the organisms were morphologically characteristic of the genus *Leptospira*[4].

The positive culture was transferred to bovine albumin 'Tween 80' with 5-fluorouracil, Fletcher's semi-solid and Stuart's liquid media. These media were adequate for growth and the isolate could be continuously subcultured.

Standard rabbit antisera against *L. ballum*, *L. canicola*, *L. icterohaemorrhagiae*, *L. bataviae*, *L. grippotyphosa*, *L. pyrogenes*, *L. autumnalis*, *L. pomona*, *L. sejroe*, *L. australis*, *L. hyos*, *L. mini georgia*, *L. biflexa*, and *L. kremastos* were used for preliminary identification of the isolate. The isolate was propagated in Stuart's medium for use in the microscopic agglutination test and the subsequent antigen standardized by nephelometry, to a nephelometer reading of 25–30 (ref. 5). The isolate reacted against *L. ballum* antiserum in a dilution of 1 : 25 with the microscopic agglutination test. Rabbit antiserum against the isolate was prepared from a liquid culture standardized to the same bacterial density as that used in the microscopic agglutination test. The antiserum produced reacted with its homologous antigen in a 1 : 12,800 dilution. The rabbit antiserum was tested against antigens of twelve leptospiral serotypes previously listed (excluding *L. biflexa* and *L. kremastos*). The rabbit antiserum reacted against *L. ballum* to an end titre of 1 : 25. The microscopic agglutination test was performed with serum from frogs 1 and 2 (*A*) and frogs 4, 5 and 6 (*B*) against the homologous isolate, *L. pomona*, *L. biflexa*, and *L. ballum*. The microscopic agglutination test was negative in dilutions of serum as low as 1 : 10. In addition, the same serum pools were tested using the rapid macroscopic slide agglutination test[1], with negative results.

Investigations have been conducted to determine the pathogenic characteristics of the isolate in guinea-pigs, hamsters, gerbils, and mice. Actively growing cultures of the frog isolate were inoculated intraperitoneally into the species. No fever or weight loss was observed in the animals following inoculation. The frog isolate has not been recovered from blood culture or from the kidneys of the experimental animals. Additional laboratory studies are in progress to determine the role of the isolate as a pathogen. The isolate has been sent to the World Health Organization/Food and Agriculture Organization and National Leptospirosis Reference Laboratories for definitive identification.

A review of the literature indicates that the role of amphibians and reptiles in the epidemiology of leptospirosis is not as well defined as in man, domestic animals, and wildlife.

In studies of frogs (*Rana* sp.), Van Thiel[6] found a high percentage of sera reacted against many pathogenic and apathogenic strains of leptospires. He states that this may be due to natural immunity which can be broken when frogs are experimentally inoculated with large doses of virulent *L. icterohaemorrhagiae*. Leptospires were recovered from the kidneys and livers up to 7 days after experimental inoculation. Van Thiel concluded that frogs under natural conditions did not shed leptospires in the urine or play a part in the epidemiology of Weil's disease. Babudieri[7] was unable to isolate pathogenic leptospires from some species of amphibians caught in the rice fields of Italy. He reports that others have had similar negative results; Uhlenhuth and Fromme found leptospires in the intestine of the frog, but Babudieri states that these were probably not pathogenic.

Combiesco *et al.*[8] and Van der Hoeden *et al.*[9] reported finding leptospiral agglutinins in the serum of reptiles. Abdulla and Karstad[10] experimentally inoculated snakes with *L. pomona*. Uninoculated snakes kept as cage mates became infected. Both groups were carriers of leptospires in liver and kidney tissues and also produced agglutinins against *L. pomona*. Two species of turtles were similarly infected by inoculation with *L. pomona*. Neither transmission of the infection to cage mates or sustained infection was observed in the turtles. In Florida, White[11] found leptospiral agglutinins in snakes, but leptospires were not isolated from the liver or kidney tissues. Ferris *et al.*[12] isolated *L. ballum* from the kidney tissue of the hog-nosed snake (*Heterodon platyrhinis*) in Illinois, but agglutinins against *L. ballum* were not detected. In Slovakia, Plesko *et al.*[13] isolated *L. sejroe* from one of thirty-seven lizards; leptospiral agglutinins were found in ten of thirty-seven tested.

Although the isolate discussed in this communication was cultured from the kidney of the frog, the role of the unidentified leptospire has not been defined as either a pathogen or a saprophyte. The significance of the 1 : 25 microscopic agglutination titre against *L. ballum* is at present unknown.

Four major questions become apparent: (*a*) What part do the poikilothermic amphibians and reptiles or other lower forms of animal life play in the maintenance and continuity of leptospires in the environment? (*b*) Lower forms of life serve as food for other animals, but are some amphibians the culprits—carriers and shedders of leptospires—or victims or both? (*c*) When pathogenic leptospires are discharged into water, do they remain pathogenic for animals and man, do they transform into saprophytic or free-living forms for survival, or do they gradually disintegrate and die? (*d*) Do lower forms of animal life become intermediate hosts and provide a missing link in the chain of transmission which results from transformation of leptospires from saprophytes into pathogens that infect other animals and man?

Further investigations of amphibians, reptiles, and lower forms of life and their environmental interrelationships may help to define the role of pathogenic or saprophytic leptospires in the epidemiology of leptospirosis.

We thank A. Ritchie, National Animal Diseases Laboratory, Ames, Iowa, for performing the electron microscope studies on the frog isolate. This investigation was supported in part by grant *CC*-00071 from the Communicable Disease Center, U.S. Public Health Service, Atlanta, Georgia.

Effect of Cellular Lipid on the Sensitivity of some Gram-positive Bacteria to Penicillins

It is possible to increase the lipid content of Gram-positive bacteria by sub-culture in nutrient broth containing glycerol and to deplete cellular lipid by treatment of the cells with pancreatic lipase.

Using benzylpenicillin, cloxacillin, methicillin and quinacillin[1] and *Bacillus subtilis*, N.C.T.C. 3601, *Streptococcus faecalis*, N.C.I.B. 8553 and *Staphylococcus aureus* (three strains) Oxford, N.C.T.C. 8452 and 100110 isolated at Queen Mary's Hospital for Children, Carshalton, we find that lipid enhancement invariably increases the resistance, as measured by the minimum inhibitory concentration for a constant inoculum of 10^3 cells/ml. and depletion invariably produces an increase in sensitivity. Results are summarized in Table 1.

Total lipid was determined by extracting dried cells with chloroform–methanol, 2 : 1, and by electrophoresis in the presence of 10^{-4} M sodium dodecylsulphate[2].

Preliminary experiments, using thin-layer chromatography and silicic acid-impregnated paper chromatography, indicated that this change in resistance could not be attributed to any particular component of the bacterial lipid as obtained by solvent extraction.

It is clear that changes in lipid content of cells markedly effect their susceptibility to penicillins and it is not impossible that such changes may occur *in vivo*, subsequent to infection.

AGRICULTURE

Paternal Effect on Grain Size in Wheat

Varieties of wheat can differ in yield of grain even when unfavourable factors such as disease, unsuitable soil nutrient status and lodging are eliminated as completely as possible. Methods of breeding for high yield could be made more objective if the physiological processes responsible for the yield differences were understood. There are two possibilities. First the assimilative capacity of the plant after anthesis may be the principal limiting factor, or secondly, the grain may be a limited sink for photosynthates, either as a result of its rate of growth or its ultimate size.

The investigation reported here was carried out to obtain information on the potential capacity of the grain as a sink for photosynthates. Tests were made for genetically determined differences in grain size. The effects of variation in grain number, and of the assimilative capacity of the plant, on the supply of photosynthates to each grain were eliminated by making comparisons using common maternal parents. Genetic differences in the grain were obtained by artificial cross-pollination.

Table 1. Naturally Selfed Parents

	Mean weight per grain (mg)
'Holdfast'	41·6
'Cappelle-Desprez'	58·4
F_1 'Holdfast' × 'Cappelle Desprez'	53·5
Least significant difference $P < 0.05$	3 3
$P < 0.01$	4·7

Two varieties of winter wheat were used: 'Cappelle–Desprez' which has large grain and 'Holdfast' which has relatively small grain (Table 1). In 1963 the varieties were crossed reciprocally and also selfed by hand, a separate ear being used for each treatment. The experimental variation was too great for a paternal effect to be detected. This effect was likely to be small, because the male parent contributes only one-third of the endosperm genotype.

Table 1. Effect of Lipid on the Sensitivity of Gram-positive Bacteria to Penicillins

Organism	Treatment	Lipid content (% w/w of whole dried cells)	Mobility (μsec^{-1} V^{-1} cm^{-1}) in the presence of 10^{-4} M sodium dodecyl-sulphate	Minimum inhibitory concentration (μg/ml.)			
				Quinacillin	Benzyl-penicillin	Methicillin	Cloxacillin
Staph. aureus (Oxford)	Control	6·39	−2·84	0 3	0·03	8·0	0·35
	Grown with glycerol	18·3	−4·56	20 0	2·0	20 0	8·0
	Lipase treated	6·4	−2·40	0 1	0·01	6·0	0·25
Staph. aureus N.C.T.C. 8452	Control	6·5	−3·21	0·7	Destroyed	1·0	0·5
	Grown with glycerol	7·0	−3·68	2 0	Destroyed	2·0	0 8
Staph aureus 100110	Control	—	−3·69	5·0	100	26	1·0
	Grown with glycerol	—	−3·68	5 0	100	26	1·0
	Lipase treated	—	−3·0	3·5	100	24	0·8
Strep. faecalis	Control	5·3	−2·42	110	3·2	45	40
	Grown with glycerol	5·9	−3·01	350	10·0	100	200
B. subtilis	Control	8·6	−4·56	8·0	0·6	0 4	0·01
	Grown with glycerol	19·0	−5·48	40	5·0	1 0	0·03
	Lipase treated	8·3	−3·45	5·0	0·3	0·2	0·008

In 1964, genetic differences in the grain were obtained by backcrossing the reciprocal F_1 hybrids, as female parents, with each variety. Therefore, owing to genetic segregation in the F_1, the genetic variation in the endosperm was greater than in the previous experiment. To facilitate crossing, the small basal and apical spikelets, and also all florets in excess of two per spikelet, were removed from the F_1 ears. To improve the accuracy, and to ensure that photosynthates were available similarly to grain in the two treatments, each maternal ear received both backcrosses, one rank of spikelets being crossed by 'Cappelle-Desprez' and the other by 'Holdfast'. The two reciprocal F_1 hybrids behaved similarly, and the results for all the 29 treated ears have been combined (Table 2).

Table 2. BACKCROSSES OF F_1 HYBRIDS BY THE TWO PARENTS

	Mean No. of grains set	Percentage of grains set	Mean grain weight (mg)
Backcross by 'Holdfast'	9·7	86 6	52 0
Backcross by 'Cappelle-Desprez'	9·4	88·1	54 0
Variance ratio	0·58 (Not significant)	0·39 (Not significant)	12·7 ($P < 0·01$)

It is apparent, from the significant paternal effect in the backcrosses, that the genotype of the grain was a determinant of grain size. Because photosynthates were available similarly for each treatment, this effect also implies that yield was not solely dependent on the assimilative capacity of the plant.

By taking other observations into account, it is possible to consider how the inter-relations of photosynthate supply and the characteristics of the developing grain determine yield. Experimental reduction of the photosynthetic area also indicates that the assimilative capacity is not always fully exploited. For example, Thorne[1] found that compensation occurred in shading experiments with barley; and Miller *et al.*[2] found, for eight varieties of wheat, a mean reduction in yield of only 10·5 per cent for complete defoliation at the ligule one week after anthesis, and 4·8 per cent when half of every leaf was removed. Yield is not, however, entirely dependent on the characteristics of the developing grain. When few grains develop on each ear, as in partially sterile interspecific hybrids and in ears which have been emasculated and only a few florets pollinated, the grains are considerably larger than normal.

Consequently, we may conclude (Fig. 1) that yield of grain depends on the assimilative capacity of the plant, the genotype of the grain and on the number of grains produced. The interactions of these characters and their effects on yield are shown by the arrows. There is not, however, sufficient information to determine their relative importance.

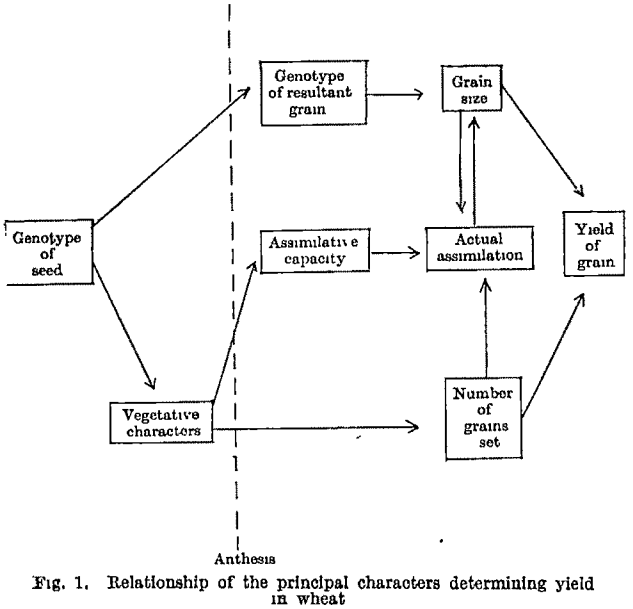

Fig. 1. Relationship of the principal characters determining yield in wheat

Because yield of grain is partially dependent on the genetic characteristics of the grain, increase in yield could be obtained by treatments which increased the number of grains set. As the number of florets per spikelet in wheat is not delimited until the later stages of ear development, the treatments, which might be of a hormonal nature, need not produce any major change in vegetative characters.

SOIL SCIENCE

Removal of Plutonium-239, Tungsten-185 and Lead-210 from Soils

THE increasing use of plutonium and the possibility of the activation of tungsten and lead by intense neutron flux produced by nuclear devices suggested a need for some investigations of the plant–soil interrelationship of these elements. Lead-210, ^{185}W and ^{239}Pu were the nuclides used.

Previous experiments in this laboratory[1] and findings of others[2] indicated that only small amounts of ^{239}Pu were translocated from the soil to the plant foliage (leaf–soil ratios $\sim 0·0001$). Data were generally variable because of the low counting rates. The results were technically improved in these experiments by the increased concentration of ^{239}Pu in the soil. Keaton[3] reported small amounts of lead accumulated in plant tissues, and Chow *et al.*[4] discussed lead isotopes in petrol and aerosols as a possible soil contaminant in areas with large numbers of cars. Limited information is available on the uptake of tungsten[5] from soils. This communication contains results showing the amounts of ^{239}Pu, ^{185}W and ^{210}Pb that were removed from different soils by plants, and the effectiveness of several extracting solutions in removing ^{239}Pu and ^{185}W from contaminated soils.

Barley (*Hordeum vulgare*, var. Arivat L.) was grown for 18 days in three different soils using a modified Neubauer technique[6]. The isotopes were mixed with 100 g oven-dry soil, then placed in a container. After planting, the soil was brought to field capacity by daily watering. The soils were: Ephrata fine sandy loam, a slightly alkaline soil; Milville silt loam, a calcareous soil; and Cinebar silt loam, a medium acid forest soil. The isotopes were added as plutonium nitrate, potassium tungstate (specific activity, 2·7 mc./mg) and lead chloride (specific activity, 81 mc./g) dry soil for ^{185}W and ^{210}Pb and 10 μc./g for the ^{239}Pu. The activity in the extraction experiments for both soils was 0·1 μc./g dry soil. The standard soil extraction procedure was used[7].

The amount of ^{239}Pu and ^{210}Pb accumulated in tissues was very limited, but ^{185}W was taken up readily (Table 1). The uptakes of these radioisotopes by barley were soil dependent, particularly that of ^{185}W. Concentration of ^{185}W in plants grown in Ephrata soil was fifty-five times higher than for those grown in Cinebar soil. The lower uptake from acid (Cinebar) soil suggests that tungsten was taken up as an anion, probably WO_4^{--}. The uptakes of ^{210}Pb and ^{239}Pu were greatest from the acid soil, which is true for most cations. No toxic symptoms were observed, and yields (Table 1) for each soil type were nearly the same with all the nuclides. Yields in controls, not shown, were not significantly different from treatment yields.

The removal of ^{239}Pu and ^{185}W from the different soils into suspending solutions is shown in Table 2. The

Table 1. Uptake of ^{239}Pu, ^{185}W, and ^{210}Pb by Barley from Three Soils using a Neubauer Technique

Isotope	Soil type	Soil activity (μc./g)	Plant yield (g)	Concentration in tissue (nc./g)	Removal by plant (per cent)
^{239}Pu	Ephrata	10	1·5 ± 0·02	1·3 ± 0·13	0 00019
^{239}Pu	Milville	10	1·5 ± 0 02	0·4 ± 0 08	0·00006
^{239}Pu	Cinebar	10	1·0 ± 0·02	2·2 ± 0·37	0·00022
^{185}W	Ephrata	0·1	1 2 ± 0·1	380 ± 5	4·5
^{185}W	Milville	0·1	1·4 ± 0·1	80 ± 5	1·1
^{185}W	Cinebar	0·1	0 8 ± 0·1	7 ± 1	0·06
^{210}Pb	Ephrata	0 1	1·6 ± 0·02	0·2 ± 0·02	0·003
^{210}Pb	Milville	0 1	1·8 ± 0 03	0·2 ± 0 05	0·003
^{210}Pb	Cinebar	0·1	1·0 ± 0·03	0·5 ± 0 05	0 005

± = One standard deviation.

Table 2. Removal of ^{239}Pu and ^{185}W from Soils using Different Extractants

Isotope	Soil	Per cent removed by the following extractants: 1·0 N NH_4 AC	0 1 N HNO_3	1 0 N HNO_3	0·2 mM DTPA*
^{239}Pu	Ephrata	0 06 ± 0 02	0·14 ± 0·01	0·25 ± 0 02	0·1 ± 0·03
^{239}Pu	Cinebar	0 05 ± 0·01	0·64 ± 0·08	0·32 ± 0·08	0 03 ± 0 004
^{239}Pu	Milville	0 06 ± 0 004	0·01 ± 0·004		0·43 ± 0·005
^{185}W	Ephrata	12 0 ± 1·0			
^{185}W	Cinebar	1·4 ± 0·2			
^{185}W	Milville	4 8 ± 0·8			

* Calcium-trisodium salt of diethylenetriaminepentaacetic acid (supplied through the courtesy of the Geigy Chemical Corporation).
± = One standard deviation

greatest amount removed was the 12 per cent of ^{185}W extracted from Ephrata soil with ammonium acetate. The removal of ^{185}W by ammonium acetate extraction, and by barley, follows the same pattern in all three soils, although the amount removed by the ammonium acetate was much greater than that removed by barley. The highest amount of ^{239}Pu removed was 0·64 per cent from the Cinebar soil by 0·1 N nitric acid. Again the extracting solutions removed much more ^{239}Pu from soils than did the plants.

Barley grown in the different soils accumulated only very small amounts of ^{210}Pb, less ^{239}Pu, whereas ^{185}W was accumulated in biologically significant quantities. These results show that the soil extracting procedures in common use are not reliable estimates of the quantities of these radioisotopes that can be removed by plants.

This work was performed in the Hanford Laboratories operated by the General Electric Company for the U.S. Atomic Energy Commission under contract *AT*(45–1)–1350.

PSYCHOLOGY

Müller-Lyer Haptic Illusion and a Confusion Theory Explanation

Many geometric visual illusions have haptic analogues[1]. The most studied is the Müller–Lyer figure. Gregory[2] has recently given strong evidence in support of a perspective theory of the visual variant. Day[3] has argued in favour of a common explanation of both—a suggestion which would rule out the perspective theory, as the haptic variant has been demonstrated on congenitally blind subjects[4]. It seems that the simplest explanation of the Müller–Lyer haptic illusion has been ignored. This is the confusion theory[5]. Under this the illusion results from the mere confusion of the arrow-heads' apices with their fins.

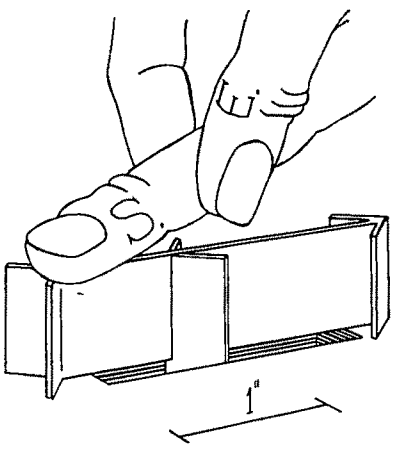

Fig. 1

In the present experiment Revesz's passive technique[1] was used. E. drew S.'s index finger from a position of rest on one end of the figure longitudinally over the rest without stopping at the other end (Fig. 1). S. then said which segment of the centre line he thought was bigger. To avoid confusion the figure was originally described to S. demonstratively by touch using the terms 'point' and 'line' only, and he was instructed to ignore the shorter lines as much as possible in making his judgments. The method of limits was used—the position of the centre arrow-head was varied along the centre line for each judgment. Two variables were investigated—the direction of finger movement and the direction in which the arrow of the figure pointed. Both could be either towards or away from S. Seven students were tested.

From the confusion explanation one would expect the three points where the centre line is intersected to be always confused with the fins except when the finger is initially placed at the pointed end. A clear impression of this point only should then be received because S.'s finger is initially at rest on this same point. Consequently the illusion should be greater when the finger is begun at the tail end of the figure. An analysis of variance confirmed this ($P < 0·001$). Contrary to expectation, further analysis showed that when S.'s finger was initially placed at the pointed end the illusion was not significant ($P < 0·15$ on a one-tail t-test).

We chose the passive technique as it appeared to give us more control over the stimulus. However, we found it a very difficult and inelegant method; S.'s hands were often too limp or too stiff or they perspired. Despite these criticisms the results seem positive enough to give some support to the confusion theory.

With this explanation, repeated inspection trials would be expected to lead to an improved perception of the figure with less confusion and a consequent decrement in the size of the illusion. This has been found by Rudel and Teuber[6] although they used a different technique and a Müller–Lyer figure five times as large as our own. They also found a transfer of decrement from touch to vision and vision to touch. This remains unexplained by our results, which endorse the view that the two illusions require different explanations.

Saturday, March 5

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S E.23), at 3.30 p m.—Mr. Nigel Heppel "A Naturalist in Nigeria".*

Monday, March 7

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. P. J. N. Norris. "An Introduction to Silicon Controlled Rectifiers".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6 30 p.m —Dr. H M. Finniston "Experimenting in Experiments".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURERS IN BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (March 4).

JUNIOR RESEARCH OFFICER (graduate) for supervisory duties in the laboratories of the DEPARTMENT OF BIOCHEMISTRY AND AGRICULTURAL BIOCHEMISTRY—The Registrar, University College of Wales, Aberystwyth (March 5).

PROGRAMMING ASSISTANTS (2) (graduates, preferably with some knowledge of computing) IN THE COMPUTING DEPARTMENT, for work which will involve programming and the supervision of programmers—The Secretary of the University Court, The University, Glasgow (March 5).

LECTURER or ASSISTANT LECTURER (with a special interest in bacteriology or microbial genetics) IN BOTANY—The Secretary, Birkbeck College (University of London), Malet Street, London, W C.1 (March 7).

UNIVERSITY DEMONSTRATOR (with an appropriate honours degree and preferably research and/or teaching experience) IN ANIMAL PHYSIOLOGY—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (March 9).

LECTURER IN NUMERICAL ANALYSIS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Leicester (March 10).

ASSISTANT LECTURER (botanist or plant biochemist) IN BOTANY—The Secretary, The Queen's University, Belfast, Northern Ireland (March 11).

ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, The University, Manchester, 13, quoting Ref. 31/66 (March 12).

ASSISTANT LECTURER or LECTURER in the field of inorganic chemistry—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (March 12).

LECTURER or ASSISTANT LECTURER IN SOCIOLOGY—The Secretary, The University, Edinburgh (March 12).

CHAIR OF NATURAL HISTORY IN THE DEPARTMENT OF ZOOLOGY—Charles H. Stewart, Secretary to the Curators of Patronage, University of Edinburgh, Old College, South Bridge, Edinburgh, 8 (March 14).

LECTURER or ASSISTANT LECTURER IN INORGANIC CHEMISTRY (in one of these appointments preference will be given to candidates with an interest in organo-metallic or transition element chemistry)—The Deputy Secretary, The University, Southampton (March 14).

LECTURER or ASSISTANT LECTURER IN STATISTICS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Leeds, 2 (March 14).

LECTURER or ASSISTANT LECTURER (one or more, preferably with research experience in either catalysis or absorption, or in techniques used in these fields) IN PHYSICAL CHEMISTRY—The Secretary, The University, Edinburgh (March 14).

ASSISTANT LECTURER (with some experience in structural petrology) IN THE DEPARTMENT OF GEOLOGY—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (March 15).

LECTURER IN RADIATION BIOLOGY AND PHYSICS—The Secretary, University of St. Andrews, Queen's College, Dundee (March 15).

LECTURER (with special interests in plant biochemistry or microbial genetics or morphogenesis) IN BOTANY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (March 15).

ASSISTANT LECTURER (with interests in sedimentology or palaeoecology) IN THE DEPARTMENT OF GEOLOGY—The Secretary, The University, Edinburgh (March 16).

LECTURER and ASSISTANT LECTURERS (2) IN PHYSICS—The Secretary, The Queen's University, Belfast, Northern Ireland (March 19).

LECTURER or ASSISTANT LECTURER (medically qualified) IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Leeds, 2 (March 21).

RESEARCH ASSISTANT or SENIOR (Post-doctoral) RESEARCH ASSISTANT IN ORGANIC CHEMISTRY for investigations related to fluorinated polymers—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (March 21).

TEMPORARY ASSISTANT LECTURER (with a good honours degree and a special interest in social geography) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leeds, 2 (March 21).

PRINCIPAL LECTURER IN SCIENCE AND HEAD OF THE SCIENCE DEPARTMENT—The Principal, Bede College, Durham (March 26).

SCIENTIFIC OFFICER (with a good honours degree, and preferably training in genetics and statistics) to engage in research on grass breeding techniques, including the evaluation of selection criteria—The Secretary, Plant Breeding Institute, Trumpington, Cambridge (March 26).

ASSISTANT LECTURER (with a veterinary degree) IN VETERINARY PATHOLOGY—The Registrar and Secretary, The University, Bristol (March 31)

CHAIR OF STATISTICS AT BIRKBECK COLLEGE—The Academic Registrar, University of London, Senate House, London, W.C 1 (March 31).

ENTOMOLOGIST or BOTANIST IN THE PLANT PATHOLOGY DEPARTMENT to work on insect transmission of viruses to plants, including cereals and grasses—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (March 31).

FELLOW (with a Ph.D. or equivalent degree in chemical engineering or one of the physical sciences) IN HIGH INTENSITY COMBUSTION OF FINE PARTICLES, University of Canterbury, Christchurch, New Zealand, to study and develop small burners capable of burning pulverized coal—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (March 31).

SECOND CHAIR IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Deputy Secretary, The University, Southampton (April 1).

SIR WILLIAM DUNN READER IN BIOCHEMISTRY—T. D. Kellaway, Department of Pathology, The University, Tennis Court Road, Cambridge (April 18).

PROFESSORS (3) OF ENGINEERING—The Registrar, University Registry, The Old Schools, Cambridge (April 19).

ASSISTANT PHYSICIST (Basic Grade) TO WORK IN THE RADIOTHERAPY DEPARTMENT AND THE CLINICAL ISOTOPE LABORATORY—The Group Secretary, Portsmouth Group Hospital Management Committee, Saint Mary's Hospital, Milton Road, Portsmouth.

CHAIR OF BIOCHEMISTRY—The Registrar and Secretary, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex, marking envelope "Confidential".

EXPERIMENTAL OFFICER (with a degree in some branch of biology) IN THE DEPARTMENT OF PATHOLOGY to work as a member of a team investigating the behaviour of children's tumours in tissue culture—Dr. J. K. Steward, Tissue Culture Laboratory, Department of Pathology, University of Manchester, Manchester, 13.

HEAD (with high academic qualifications and considerable research experience in laboratory and field experimentation with crop plants, not necessarily vegetables) OF THE CHEMISTRY SECTION—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick.

LECTURER IN SOCIOLOGY IN THE DEPARTMENT OF ARTS, SCIENCE AND EDUCATION—The Registrar, Goldsmiths' College (University of London), London, S.E.14.

LECTURER or ASSISTANT LECTURER (preferably with knowledge of one or more of the following fields: process control and dynamics, mass and heat transfer, particle mechanics, thermodynamics, or chemical reaction engineering) IN CHEMICAL ENGINEERING—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 59/2/G.

LECTURER or SENIOR LECTURER (honours graduate with a special interest in mycology and plant microbiology) IN BOTANY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

LECTURER (well qualified in physics and preferably experienced in some branch of advanced electronics) IN THE DEPARTMENT OF PHYSICS—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

LECTURERS or ASSISTANT LECTURERS (or exceptionally Senior Lecturers or Readers) IN NUMERICAL ANALYSIS—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex.

POSTDOCTORAL FELLOW IN THE CHEMICAL LABORATORY for work in carbohydrate chemistry with Dr. R. D. Guthrie—The Assistant Registrar (Establishmert), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex.

RESEARCH ASSISTANT (with a first degree in a biological science) IN THE DEPARTMENT OF ZOOLOGY to work on problems of cell behaviour in tissue culture—The Secretary, University College, Gower Street, London, W.C.1.

RESEARCH ASSISTANT (honours graduate or graduating this summer) IN BOTANY—Head of the Department of Botany and Zoology, Sir John Cass College, Jewry Street, London, E.C.3.

RESEARCH PATHOLOGIST or HISTOLOGIST for work on atherosclerosis—Dr. E. B. Smith, Courtauld Institute of Biochemistry, Middlesex Hospital Medical School, London, W.1.

SENIOR LECTURER (well qualified academically and practically in present-day methods of analysis including instrumental analysis) IN ANALYTICAL CHEMISTRY—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 1/G.

STATISTICIAN or AGRONOMIST (with good statistical experience) to assist research workers in developing countries overseas in the design, conduct, and interpretation of experiments on perennial plantation crops—The Secretary, East Malling Research Station, East Malling, Maidstone, Kent.

TECHNICIAN, and JUNIOR TECHNICIANS (2) IN THE DEPARTMENT OF PHYSICS—Mr D. R. Ringer, Department of Physics, The University, Nottingham.

Pye precision in gas chromatography

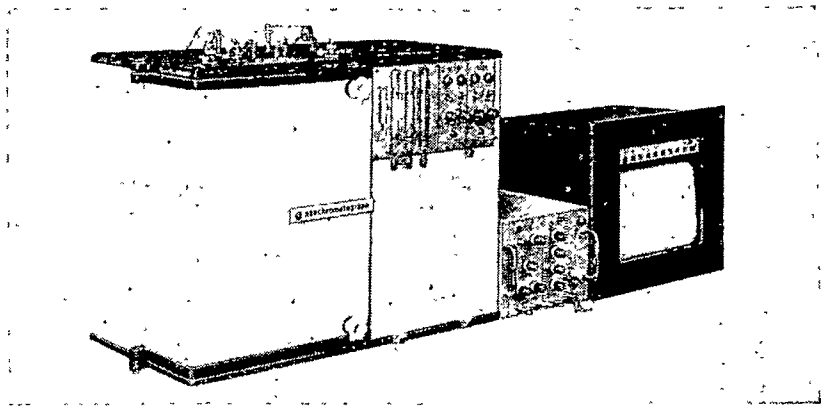
Oven accommodates interchangeable head units incorporating different detector and column configurations and is designed for isothermal or programmed temperature control.

Oven head unit with dual flame detectors, columns and injection ports.

NEW PYE SERIES 104 CHROMATOGRAPHS SPEED ROUTINE ANALYSES

Analysts are changing to the new low-cost Series 104 Chromatograph because its greater speed and convenience save money. They have acknowledged the functional design, the simplified operating features, the comprehensive specification and the overall economy of the system. They are now experiencing its complete reliability under continuous operating conditions.

Four versions of Series 104 are available which cover everyday analytical applications, including steroids, fatty acids, wide boiling range mixtures and high boilers.



The Pye Series 104 Chromatograph gives *faster analysis* with warm-up rates of up to 48°C per minute and operating temperatures as high as 500°C, *easier analysis* due to excellent oven accessibility and design of controls, and *cheaper analysis* with lowest possible outlay and maintenance costs.

Moreover, the Pye Series 104 is designed for continuous development and updating as new techniques emerge.

Please send for the new 20 page illustrated brochure which provides all the technical facts and figures including oven performance data.

PYE PANCHROMATOGRAPHS AID RESEARCH

Leading research establishments in many parts of the world depend upon the versatility of the Pye Panchromatograph to satisfy their most stringent requirements including investigations into the technique and the teaching of gas chromatography. This analytical system can accommodate different detector combinations and column arrangements in two independent ovens, and it features a patented column effluent splitting device which permits further analysis of the column outputs. Numerous optional features including temperature programming, pyrolysis, preparative scale and radiochromatography are available. The Pye Panchromatograph is the first choice for an all-purpose instrument for research.

The Panchromatograph will accommodate six different types of detector, singly or in pairs.

the original and best variable transformers

THE VARIAC* variable transformer is the most useful and versatile device ever developed for the control of a.c. voltage, or of current, power, heat, light, speed It provides smooth continuous adjustment of output voltage from zero to line voltage and above, either hand-operated or motor-driven.

There are over 600 Variac models and assemblies to suit virtually every possible requirement, ranging from small units for laboratory or instrument use to large ganged assemblies for high power 3-phase operation. The range includes low-voltage, high-frequency, dual-output and narrow-range types, open, covered, portable, metalclad and oil-immersed constructions, plus many special models. This is the largest range of variable transformers available today.

The technical superiority and dependability of Variac are the result of over 30 years of development and refinement since the introduction of the first Variac models—the *original* variable transformers.

**'Variac' is a registered trade mark*

Variacs are made in England by The Zenith Electric Co. Ltd., London, and exclusively distributed in the U.K., Eire and British Colonies by Claude Lyons Ltd

Lock

Gas Chromatograph Test Set & Reference Signal Source

enables the Chemist or Instrument Engineer to check quickly the operation and performance of his complete Gas Chromatograph equipment.

If the equipment is not operating correctly, it will quickly localise the faulty section.

No electrical knowledge is necessary to use this Test Set, which is suitable for Flame Ionisation, Thermistor type and Katharometer Gas Chromatographs.

Please write for details now:-

NEW UNICAM SP700

recording spectrophotometer

now choose **WAVELENGTH** (SP700A)
or **WAVENUMBER** (SP700C)

plus these other advantages

HIGH performance over wide spectral range 186mμ – 3.6μ
FIVE linear transmittance and three linear absorbance scales
FIVE scanning speeds and three chart speeds
BEAM balance adjustment for base line stability
IMPROVED layout of controls
SAMPLING accessories include diffuse reflectance attachment

send for further details today

UNICAM Precision Spectrophotometers

UNIVERSITY LIBRARIES FOR THE FUTURE

IN the debate on higher education in the House of Lords on December 1, Lord James of Rusholme remarked that the money available to buy books for the new library at the University of York was less than one-half of the amount which may be available for equipping a new science laboratory for a single science subject. This absurdity is attributable to the fact that scientific apparatus seems more obviously and materially useful than books; however, as Lord James added, books are just as essential pieces of apparatus to the scientist as a cathode-ray tube or a spectrometer. Lord Holford endorsed the point in respect of the situation at the University of Kent at Canterbury, where there is no public library capable of helping out deficiencies in the central university library.

This particular point was not mentioned by the Earl of Longford in replying on the debate, and this, together with the dilatory attitude of the Committee on Libraries set up by the University Grants Committee and the Ministry of Education, and the naïve remark in the Robbins Report that "a library adequate to scholarly research is as essential to the efficient running of a university as an adequate range of computers", fully justifies the anxiety expressed recently by the Master of Sidney Sussex College, Cambridge (*The Listener*, 75, 47; 966). Universities, as Dr. D. Thomson pointed out, have managed for centuries without computers, but never without libraries. He suggested that the Government's decision not to establish further new universities for 10 years might at least offer some protection against ridiculously inadequate university libraries. His protest against the lack of realism in some of the handling of university expansion is timely, but nowhere more so than in his reference to the position of the university library. It is to be hoped that the Minister for Education and Science, who now bears the main responsibility for policy in this regard, will pay some attention to the addresses and reports of Paul Buck, director of Harvard University Library, now published by the Oxford University Press, under the title *Libraries and Universities*. There is much in the volume which the Minister might use to emphasize the futility of the Government's present attitude to university expenditure: "You cannot have a quality education without a quality library. . . . The Harvard Law School is a great school; it also has the greatest legal library in the world. These two facts are related. . . Library growth, unlike growth in most other parts of a university, is cumulative". Comments like these make nonsense of a Government policy which results in situations such as those described by Lord James and Lord Holford.

This is one context, at least, in which it is worth considering the lecture, "The Ecology of Inter-Library Loans", delivered last April by Dr. D. J. Urquhart at the Conference of the University and Research Section of the Library Association at Reading and published in the *Library Association Record* (67, 341; 1965). Dr. Urquhart was concerned not merely to describe the present position of inter-library lending, but also to indicate the direction of change and to outline new approaches. He noted, for example, that the annual output of publications in science and technology has been doubling every 15 or 20 years for the past three centuries and, even outside this field, is doubling perhaps every 20–25 years. The average audience for a learned publication, however, remains about the same, because of the parallel increase in readers, with the important consequence that the volume of rarely used material is expanding rapidly. Dr. Urquhart points out that the normal worker needs to know what publications exist on his subject quite irrespective of whether the library holds them, and he argues that sooner or later libraries must become more concerned with helping readers to discover what exists and less with describing what particular publications they hold.

When this happens, the demand for inter-library loans is likely to increase considerably. Dr. Urquhart suggests that at present few librarians are keen to advertise the inter-library lending system. He maintains that as the system developed under the National Central Library, the copyright libraries, which had most to contribute and the least to gain, held aloof. Nor have schemes of co-operative purchasing, while increasing the availability of British books, removed gaps in the national coverage. He rejects also the view of the Roberts Committee, in its report on the *Structure of the Public Library Service in England and Wales*, that most of the work of the National Central Library related to the needs of local libraries. In 1963–64 only 44 per cent of the requests received by the National Central Library came from public libraries, and a more recent survey has shown that, of publications supplied through the National Central Library, only 16 per cent came from public libraries.

Inter-library loans, according to Dr. Urquhart, are marginal to the public library service, providing only 0·1 per cent of its issues, but they are of major importance to libraries serving universities and research organizations, and provide university libraries with about 5 per cent of their issues. The National Lending Library for Science and Technology decided against a regional system, however, partly because the postal service was regarded as reasonably efficient and partly because statistical considerations indicated that it would be more efficient to centralize. A central library with five copies can provide a better loan service than five regional libraries each with one copy. The output from the National Lending Library for Science and Technology has doubled over the past 2 years and is at present about equal to the combined output of the National Central Library and the regional system.

Dr. Urquhart also questions the value of union catalogues and suggests that the question whether an adequate service could be provided if the union catalogues were more complete, or what degree of completion is desirable, requires examination. He also advocates some operational research on the regional bureaux of the National Central Library. While insufficient information for reliable decisions is at present available, he believes that no service based on union catalogues can be as rapid as one based on a central collection, as with the National Lending

Library for Science and Technology. Dr. Urquhart does not mention, however, that the latter has recently come under some criticism regarding the extent of its holdings.

Dr. Urquhart goes on to discuss the problem of creating a 'national lending library for the humanities' on the pattern of that established at Boston Spa for science and technology. The absence of a prototype such as the Science Museum Library makes the problem much more difficult than it was in the sciences, and Dr. Urquhart concludes that it is first necessary to develop a prototype for the humanities which should be accessible, so that the importance of accessibility to the shelves can be tested. Meanwhile, the existing resources should be reviewed to see what alternative action is possible.

He does not believe that a survey of library resources is required, but strongly urges the full participation of the copyright libraries in library loans. The British Museum should take the lead as the library with the major collection in the humanities, possibly developing at least a prototype for the National Lending Library for the Humanities. The new trustees, he suggests, should urgently review the possibility of such a national library becoming more actively concerned with the inter-library loan arrangements. Alternatively, he suggests that the prototype might be based on the London Library or the Senate House Library, or possibly on the National Central Library itself, if it were transferred north of Birmingham and made primarily a library.

What is done will clearly depend on how far and how fast the various organizations are prepared to move, but it will be noted that Dr. Urquhart contemplates that some of the university libraries will move towards providing an active loan service. Such a development is an argument for augmenting rather than for curtailing the services a university library can offer and the resources it can command. What is clear from Dr. Urquhart's address is that the university library should be seen both as an essential element in the effective functioning of any university institution and as an integral part of a national library service. From either point of view it is false economy to starve the university library of resources, whether in buildings, equipment, books, periodicals, new techniques, or staff.

Dr. Urquhart's choice of the term 'ecology' demonstrates the proper approach to the development of the university library as well as to library co-operation. We are concerned with a dynamic and not a static situation. Not the least of the dangers attending ill-timed 'economy' is that it prevents forward planning and may involve far greater expenditure in ineffective attempts to overtake arrears. If the order of priorities is wrong, waste and inefficiency are inescapable. Two further comments may be added. First, Dr. Urquhart is not unmindful that his proposals for concentration and for drawing in the copyright libraries might involve difficulties in the way of personal use of reference libraries. This risk should be minimized by the holding of several copies where possible, quite apart from greater use of photocopies. Moreover, as he points out, it is neither economic nor reasonable for individuals to travel long distances to reference libraries unless they have a number of items to consult, some of which would always be available.

The second point concerns the possibility of abuse of inter-library lending by some libraries seeking to borrow items which are in print and could much more cheaply be obtained that way. Dr. Urquhart rather discounts this possibility, but any system is open to abuse by those who are so minded. It should not, however, be difficult to discourage frivolous and unreasonable requests by instituting a suitable charge for each inter-library loan application form. Apart from thus increasing the incentive to buy rather than to borrow, the sum charged could be divided between the National Lending Library and the library making the loan, thus covering the loan expenses and helping the participating libraries to build up their stock of books. Given the vision and the determination which have so far been completely lacking on the Government side, Britain could easily have a library service and system in which the university libraries could play their fitting part and one entirely adequate to meet future expanding needs.

ORGANIZATION OF RESEARCH ESTABLISHMENTS

The Organization of Research Establishments

Edited by Sir John Cockcroft. Pp. 275 + 4 plates. (London: Cambridge University Press, 1965.) 63*s*. net; 11.50 dollars.

IN the final chapter of *The Organization of Research Establishments*, Sir Edward Bullard makes the significant point that as little as a half-century ago large-scale research establishments operating apart from universities were virtually non-existent. There were, indeed, Government organizations devoted to aspects of science and technology, such as the British National Physical Laboratory, the Physikalisch-Technische Reichsanstalt in Imperial Germany, and the Bureau of Standards in the United States. There were also differentiated research laboratories in a few leading industrial corporations such as the General Electric Company, the Du Pont Company, and the Bell Telephone Laboratories in the United States. But all these organizations for research and development were both comparatively small and relatively restricted in outlook. The broader tradition of scientific research was still so largely confined to university environments that many of the pioneers in the early institutes thought long and hard before they were willing to forsake those environments, from which a large share of them came.

How extraordinarily this picture has altered in recent years requires no emphasis. Even before the Second World War both industrial and Government research organizations in Great Britain had expanded greatly, in size, in numbers, and in the range and depth of their professional concerns. But it was only during and after that war that really large-scale establishments devoted primarily to research and development, formally divorced from universities and largely supported, directly or indirectly, from public funds, became familiar, at first primarily in connexion with weapons development, later in much more varied roles. Since then it has become apparent that this evolution reflected another and quite fundamental recent social change. The general public view of scientific research and development as functions of central importance both to the economic and cultural welfare of society, rather suddenly achieved, has made those activities proper—and indeed imperative—concerns of all the people, and therefore important and rapidly expanding responsibilities of Government. The implications of this shift for the organization and function of research establishments are many and profound.

Sir John Cockcroft, in his introduction to *The Organization of Research Establishments*, points out that Great Britain has been spending about £65 million a year on basic research, about £320 million a year on applied research and development, and about £245 million a year on defence, with its own requirements for research and development. In the United States increases of both total and public spending in these areas have been little less than explosive. In 1954 total expenditures for

research and development approximated 5,600 million dollars. Within a decade they increased to about 18,700 million dollars. In 1964, moreover, about 70 per cent of all the research and development performed in the nation was governmentally financed, and the Government indirectly supported about 60 per cent of the research and development undertaken by industry. Similar trends characterize other industrial nations. Sir John notes that the total volume of research and development in France and Germany comes to about half that in Great Britain, but both are expanding rapidly.

Thus organizing and administering large and complex organizations for the conduct of research and development, commonly with material support largely or entirely publicly provided, has become a skill of great contemporary importance to society. It has always been a complex and difficult art. But present circumstances have so augmented the extent and subtlety of the challenge as to create, in many aspects, virtually a novel field. Neither the task itself nor the modes of accomplishing it have ever been clearly defined. Indeed, both vary so enormously from situation to situation as to make it very doubtful that any general definition is possible. In such circumstances, a series of concrete illustrations drawn from specific cases can be far more instructive than any effort, however well conceived, to formulate abstract generalities.

It is just this quality of concreteness that makes the present work especially pertinent and valuable. The volume contains discussions of the problems of organizing and conducting research and development in eleven British establishments. They comprehend a remarkably broad range, in terms of substantive concern, of mission, and of structural size and complexity. Each is presented by an authority uniquely experienced in the organization of which he writes. Included are accounts of the National Physical Laboratory, by Sir Gordon Sutherland; the Royal Aircraft Establishment, by Dr. M. J. Lighthill; the Atomic Energy Research Establishment at Harwell, by Dr. F. A. Vick; the National Institute for Medical Research, by Sir Charles Harrington; the Medical Research Council Social Psychiatry Unit, by Sir Aubrey Lewis; the Agricultural Research Council Institute of Animal Physiology, Babraham, by Dr. J. H. Gaddum; the Empire Cotton Growing Corporation and the Organization of Research on Raw Cotton, by Sir Joseph Hutchinson; the Glaxo Organization, by Sir Harry Jephcott; Co-operative Research in the British Iron and Steel Industry, by Sir Charles Goodeve; British Railways Research and Development, by C. C. Inglish; and the Rutherford High Energy Research Laboratory, by Dr. T. G. Pickavance. There is also an account of the Bell Telephone Laboratories in the United States by Dr. J. B. Fisk, of particular interest not only in itself but for its comparative value, and one of "CERN: the European Organization for Nuclear Research", by Dr. J. B. Adams, representative of the new pattern of co-operative international effort. These thirteen essays are prefaced by the introduction by Sir John Cockcroft already mentioned, and concluded with a most interesting discussion of "What Makes Good Research Establishment?" by Sir Edward Bullard. The wide range of research and development organizations involved, their variety in size, in purpose and in substantive concerns, provides a rich inventory of comparison. Interesting contrasts abound.

Every reader will surely draw his own insights from these suggestive accounts. One element that repeatedly emerges is the continuing and critical significance of the structure and conduct of university-based research. From the beginning, the organization and the quality of university-based research have been of central importance in guiding the independent institutes and maintaining their standards. The universities have provided the orientation and the training that have qualified for his post almost every senior member of the independent research establishments, including their administrative staffs. Obviously it is of the utmost importance that the integrity and quality of university training and research be sustained in the future. Such considerations bear significantly on the issue, at present prominent both in Great Britain and the United States, as to whether it is desirable for independent research institutes to be empowered to establish training courses within their own establishments, conducted entirely independently of conventional university channels, but authorized to certify students for advanced research degrees. The question is touched on in the present volume.

The essays repeatedly emphasize by example the degree to which energy and talent devoted to administrative matters must increase relative to that dedicated wholly to substantive concerns as the size and the structural complexity of an organization devoted to research and development increase. The inherent necessity of this shift, emphasized especially in the concluding chapter, is evident. Yet there is also the ever-present countervailing danger that such an evolution, if one-sided, may jeopardize the whole tone of the effort. So the question, "Is size, *per se*, a good thing?" presents a special challenge. Some possible answers are reviewed, particularly in the chapter on the Royal Aircraft Establishment. Some of the ways in which the organizational requirements posed by size and by activities primarily directed to development, with accompanying structural articulation, and the requirements of flexibility and freedom so essential to groups concerned primarily with research can be mediated to draw maximum benefit from their interaction are particularly well illustrated in the discussion of the Bell Telephone Laboratories.

The special opportunities available for the type of research organization designed to serve a number of industrial 'clients', and some of the problems that accompany them, are well illustrated in the description of the work of co-operative research in the British Iron and Steel Industry. Similar opportunities and challenges, set in a rather different context, appear in the account of the structure and mission of the Atomic Energy Research Establishment at Harwell. The special problems and special opportunities of the research and development 'condominia' at the international level are vividly illustrated in the history and description of CERN.

A matter of unusual interest and significance, repeatedly suggested, touches the relation between age and stability in a research and development organization, on one hand, and its freshness and creative potential, on the other. The question has special contemporary relevance. For, as Sir Edward Bullard remarks, it is becoming clear that the doubling of scientific activity every 5 or 10 years to which we have become accustomed and adjusted in the immediate past can scarcely persist much longer. Deceleration may well be with us soon, and the problem of how to maintain the freshness and the creative productivity of establishments which are both becoming older and are ceasing to grow at their former rates could become very significant. Efforts to solve it could evolve more general and discerning understanding than we have at present of the deeper and more subtle elements that preserve health and promote success in the research environment.

In sum, *The Organization of Research Establishments* is unusually suggestive and valuable, and its appearance is remarkably timely. Coming when expansion and change in organization for research and development are still occurring at almost record speeds, but also at a time when those rates could begin to level sharply, the work is especially significant as a primary source.

If any minor regret is to be registered, it is that—no doubt because of unavoidable exigencies of preparation and composition—most of the accounts were apparently finished approximately four years before the appearance of the volume. Some significant changes have occurred in that time. The Department of Scientific and Industrial

Research, for example, has disappeared since the main accounts of the National Physical Laboratory and of Co-operative Research in the British Iron and Steel Industry were written. The Ministry of Science has been transformed. The account of the activities of CERN extends only to 1961. But these are minor matters indeed against the background of the scope and penetration, the quality and the potential usefulness of this book for all those concerned with the organization, the administration, and the structure of establishments devoted to research and development. CARYL P. HASKINS

TRAINING THE TECHNICIAN

Technicians Today and Tomorrow

By Dr. J. T. Young. Pp. xvii+222. (London: Sir Isaac Pitman and Sons, Ltd., 1965.) 30*s*. net.

THE timeliness of Dr. Young's book, which Sir Willis Jackson emphasizes in his foreword, is indicated not only by the establishment of the new training boards under the Industrial Training Act but also by the announcement by the Committee on Manpower Resources for Science and Technology that the triennial survey of manpower will in future cover technical supporting staff, though we may well question that Committee's view that we must await that survey before ascertaining how far the present position for educating and training is sufficient. The Carr Report and other studies of industrial training for skill have tended to concentrate on the apprenticeship system and its shortcomings, but in *Technicians Today and Tomorrow* Dr. Young does something to redress the balance. The book should do much to promote a clear understanding of the function of the technician and a wider recognition of the growing importance of the wide range of such workers. In doing so, it could also assist to alleviate another anxiety of the Committee on Manpower Resources, for such a public understanding is a powerful factor in establishing the greater esteem which could help to attract more young men and women into such careers.

Dr. Young, moreover, is fundamentally pragmatic and his clear analysis of the needs of the technician in education and training indicates the lines on which immediate steps could be taken to fill a serious gap in our provision for technical education. He provides an admirable guide, in fact, to the whole situation, for a chapter on defining the technician, followed by one giving a clear but concise historical review of the developing relations in Britain between education and industrial training, is succeeded by two in which the 1961 White Paper on "Technical Education" and the White Paper of 1962 on "Industrial Training and the Subsequent Industrial Training Act" are summarized and appraised. On this basis, he rests his detailed proposals for meeting the needs of technicians which occupy the next three chapters, and finally he considers the future position of technicians and their needs.

Dr. Young's approach is thus balanced and practical and his comments are no less sane and constructive. He faces the difficulty of defining a technician, recognizing that both the functional (or occupational) approach and the educational approach have their disadvantages. For the purposes of his book, he defines a technician as one "expert in applying specific proven techniques associated with science and technology; in particular, one who has undergone a systematic course of instruction related to those techniques". He attributes the shortage of technicians in Britain, in part at least, to the general academic nature of secondary school curricula and to prevailing attitudes towards technical education as a whole—a point which should not escape the notice of Prof. Dainton's present enquiry or of the Schools Council. He is forthright on the inadequacy of part-time education and its failure to produce results which justify its existence, and much more than the present nominal support for day release is, in his view, required before sandwich courses become extensively established in this field.

Some trenchant criticism of the British apprenticeship system is less relevant to his main theme, in which insistence on the provision of adequate finance and on the anachronism of the division between education and training recurs repeatedly. Better opportunities in technical education, whether for technicians or for others, cannot be provided on the cheap. Likewise, Dr. Young insists on the necessity of willing co-operation from both sides of industry, and neither the employers nor the trades unions escape criticism. Speedy implementation of the Industrial Training Act, coupled with a massive campaign to illumine its objectives and the urgency of the situation it has been designed to rectify, are imperative. Furthermore, when it comes to practical details, Dr. Young demonstrates that the requirements of technicians are both specific and widely different, so that they must be met by programmes adapted to those needs as well as to the nature of the educational system and the arrangements for industrial training. Here he is challenging as well as constructive, and on the transition from school to work he writes with insight and sensitivity to the needs of the adolescent. Throughout, his book is admirably designed to restore the perspective of the training of technicians which was to some extent distorted by the Robbins Report and to establish the technicians in their rightful place in industry and society, with all that that implies in terms of educational opportunity, status and financial resource. Sir Willis Jackson rightly directs attention to this matter of public esteem, and Dr. Young's book is well designed to apply some corrective to any overshadowing of the technical institutions by institutions at university level. It is a point that those over-anxious to promote equality of opportunity commonly overlook, but unless the difference is appreciated and due allowance is made for it the nation will not reap the full advantage of the services of an increasing number of scientists and technologists because they lack the support of a sufficient number of technicians. Not the least merit of the book is an admirable bibliography, while notes are appended on the emergence of the industrial technician, on the place of the National Certificate, and on the financing of technical education. R. BRIGHTMAN

COMPUTERS IN PROCESS CONTROL

Digital Computer Applications to Process Control

Edited by William E. Miller. (Proceedings of the First International Conference held September 21–23, 1964 Stockholm, Sweden, sponsored by the International Federation for Automatic Control and the International Federation for Information Processing.) Pp. xxi+595 (Pittsburgh, Pa.: Instrument Society of America, 1965 Distributed by Plenum Press, New York.) 17.50 dollars

THE first application of a digital computer to the on line control of an industrial process was made in the United States in 1958. It aroused very great interest and was followed by a wave of further applications and of activity by computer manufacturers. Generally speaking, the users were secretive about the results obtained and, at the end of 1964, it was possible to hold either an optimistic or a pessimistic view of benefits and future prospects of this development.

In September 1964 a conference was held under the joint sponsorship of the International Federation for Information Processing and the International Federation for Automatic Control to discuss the experience with these installations. A considerable body of information was released by the users, much of it for the first time, and the record of the conference, therefore, stands as an important landmark. From the published papers a better and mo

balanced judgment can be made than was possible from the previously published literature.

The picture which emerges is a mixed one. There have been the expected difficulties with hardware for measurement and actuation, and reliability was a problem in the earlier machines. The programming and engineering effort has often turned out to be greater and more expensive than was anticipated. Nevertheless, many of the users have decided that computer control already offers benefits which cannot be obtained in any other way. The financial benefits have often been good and the cost of an installation may be recovered in 18 months.

To some extent, however, the favourable economics have been due to an element of subsidy by the computer manufacturers, some of whom have recently been driven out of the field. There also remain unsolved problems in the theory of control—at present our capacity to exploit the great potential power of computers, for control is limited not only by our ignorance about the behaviour of processes, but also by the lack of effective design methods for complex control systems. One may guess that the conference marked the end of an early phase of wide-ranging experiment and the beginning of a longer, slower, but in the end more solid development.

The papers are divided into four groups, dealing respectively with chemicals and oils, iron and steel, electric power, and various other applications. In the first group are papers by Monsanto (dealing with a multi-computer system, mainly supervisory, on a large site), Imperial Chemical Industries (dealing with direct digital control), B.A.S.F. (direct digital control and optimization) and Shell (basic philosophy). The second group includes papers from the Steel Company of Wales (hot strip mill), Samuel Fox (cut-up line) and the U.S.S.R. (general survey). Power companies are represented by papers from England, France and Italy. In the fourth group are papers on a gas pipe-line network, on paper, cement, railway operation, and transport at an iron-ore mine. In addition to those mentioned, there are papers by a number of computer manufacturers on applications with which they have been concerned. H. H. ROSENBROCK

ARCH DAM STRESS ANALYSIS

Theory of Arch Dams

Edited by J. R. Rydzewski. (Papers presented at the International Symposium held at Southampton University, April 1964.) Pp. x+786. (London and New York: Pergamon Press, Ltd., 1965.) 252*s*. net.

THEORY of Arch Dams, edited by J. Rydzewski, appears on the spine of this book, the implication being that it is a text-book with a unified approach to the whole subject. In fact, the title represents the proceedings of the 1964 symposium at Southampton, which was mainly confined to elastic stress analysis of arch dams under hydrostatic loading. The twelve guineas charged by Pergamon Press seems high when compared with the sixty shillings charged for the proceedings of the conference on "Wind Effects on Building Structures" held at the National Physical Laboratory.

The eighth international congress on "Large Dams", held at Edinburgh in May 1964, brought many eminent people to the United Kingdom; advantage was taken of this to arrange the symposium between them and members of the International Association of Shell Structures, so that the usefulness of shell theory for arch dam analysis could be considered. The resulting papers present a valuable record of present-day research into the orthodox method of analysis and into attempts to apply finite difference, finite element and shell theories to arch dams. The proceedings of the symposium, therefore, do much to acquaint the dam engineer with new methods which might eventually prove useful in dam design.

Dam design is a difficult and fascinating branch of civil engineering; it requires men of wide vision, not only capable of assessing the impact of a dam on the economy of a nation, the hydrological aspects and the geophysical problems, but also possessing the technological skill to choose and design the right kind of dam (earth, rockfill, gravity or arch dam, etc.). Many factors used in the elastic analysis of dams can only be assessed in broad terms, but they can, nevertheless, have effects of over-riding importance on the results. Elastic analysis is thus only one step along the path followed by the engineer in designing a dam. A complete and elegant elastic analysis of arch dam structural behaviour does not yet exist, and it should prove of considerable help when found.

The most widely accepted method of arch dam design is the 'Trial Load Method', which the U.S. Bureau of Reclamation has developed. In essence, the dam is divided into notional arches and cantilevers, and equilibrium is satisfied while compatibility is enforced at the intersections of the arches and cantilevers only. A valuable set of papers by Copen, Beaujoint and others record recent developments in this method. There is the suspicion that sometimes the true modes of structural behaviour may be obscured by enforcing cantilever and arch action.

Probably the best way to improve the elastic analysis of arch dams is to devise techniques for solving the three-dimensional equations of elasticity and to take advantage of the ever-increasing facilities offered by digital computers. The difficulty of this is shown by Allen and Windle's solution for the simplest case of a symmetrical circular arch dam of constant thickness in a symmetrical rigid valley. They used finite difference methods with higher order corrections leading to some 450 equations, which have been solved after what must have been considerable effort. My experience is that 450 equations are not enough to represent the three-dimensional stress field with adequate accuracy, and that 2,000–5,000 equations are needed, which in turn requires special computer techniques. Otter's paper on dynamic relaxation describes one such computer technique.

A very powerful group of papers by Parme, Herzog, Tottenham and others apply the shell theories with elegance. Modes of structural behaviour other than arch/cantilever action are permitted; however, the shell theories are approximate and impose their own limitations; for example, the Kantorovitch theory does not allow any upstream deflexion. A more serious aspect, though, is the limitation of the validity of the theories to the thin zones of arch dams.

Finite element methods have been used most successfully in aircraft design; papers by Clough and Zinkiewicz give lucid accounts of the first attempts to apply the methods to arch dams.

Rocha has contributed a most valuable review paper, and the problems of rock mechanics and concrete properties are introduced by Stagg and Newman respectively. This group of papers is a timely reminder of other gaps in our knowledge, such as the need for a good failure criteria for concrete under tri-axial states of stress including uplift pressures. A. C. CASSELL

ASPECTS OF OXYGEN THERAPY

Hyperbaric Oxygenation

Proceedings of the Second International Congress, Glasgow, September 1964. Edited by I. McA. Ledingham. Pp. xi+472. (Edinburgh and London: E. and S. Livingstone, Ltd., 1965.) 70*s*.

THE second international congress on "Hyperbaric Oxygenation" was held in Glasgow during September 1964; it was very appropriately dedicated to Sir Charles Illingworth.

The programme was divided into nine parts and subjects discussed ranged from a consideration of the dangers of hyperbaric environments in general, to the use of hyperbaric oxygen in the treatment of respiratory and cerebrovascular diseases, myocardial infarction, infections and shock.

The effects of hyperbaric oxygenation on man and experimental animals as well as on aerobic and anaerobic micro-organisms were considered, from both the physiological and clinical points of view. Such fundamental problems as the design of small transportable pressure chambers and face masks were also discussed. The communications related primarily to applied aspects of the subject, with reference to human disease processes, but the response of animals with similar but experimentally induced lesions was also considered. *Hyperbaric Oxygenation* provides interesting and useful information on problems associated with working under compressed air and on methods for assessing blood-flow through particular organs or regions of the body.

The papers of Drs. Walder and Davidson on the hazards of compressed-air workers, and more particularly of 'sand-hogs' (that is, men digging under-water tunnels. where compressed air has to be used in order to keep out the water), clearly demonstrate the risks involved and the importance of expert supervision, as well as the difficulties in detecting symptomless defects of the respiratory or osseous systems during the selection of supposedly normal personnel and in the assessment of damage due to gas pressure. The adverse effects of atmospheric pollution, smoking and respiratory infections on the response of emphysema patients to hyperbaric oxygen therapy were demonstrated by Dr. Yanda, and clearly emphasize the importance of obtaining gases free from contaminants, or with only minimal contamination, for compressed-air chambers and for use in hyperbaric oxygen therapy or experiments.

In the section devoted to particular biological systems or organs, the effects of hyperbaric oxygen in experimental animals were discussed, together with reports on the use of oxygen therapy in the treatment of natural human disease processes.

The results of a clinical trial of oxygen at pressures of 1 and 2 atm. absolute in the treatment of acute myocardial infarction were presented by the Glasgow workers. No statistically significant improvement in mortality figures, as compared with those obtained by conventional therapy, was observed during the first six weeks after infarction. Furthermore, there was no significant difference in response of patients treated at the two different gas pressures. The findings of other workers in different conditions were, however, more encouraging, and Dr. Foster reported a definite improvement in results, as assessed by the sterilization of primary tumour, when radiotherapy was combined with hyperbaric oxygen at 3 and 4 atm. absolute. Good results were also reported by Prof. Hutchison and Dr. Kerr, and by Drs. Van Gool and De Jong, following the treatment of asphyxia neonatorum and retinal vascular insufficiency by hyperbaric oxygen. Final conclusions with regard to the efficacy of this procedure in the treatment of a variety of disease processes must await the results of more extensive clinical trials as well as reports on the relative merits of different programmes and techniques for oxygen administration.

Few toxic effects were reported during or after administration of oxygen at a pressure of 1–3 atm. absolute for periods of 30–60 min. For therapeutic purposes, the exposure was usually repeated on a number of occasions and after different time intervals. Using a pressure of 3–4 atm. absolute, oxygen convulsions were observed by Foster in less than 1 per cent of exposures and no permanent damage was observed.

An instructive account of the use of ^{85}Kr for the measurement of cerebral blood flow was presented by Dr. Lassen, and this provides a useful review of a technique which is at present finding wide application in the field of circulatory physiology and pathology.

The reports on the effects of oxygen at a pressure of 2 atm. absolute on bacteria are in accord with a number of previous accounts in so far as they demonstrate the ability of oxygen to inhibit the growth in a variety of anaerobes, aerobes and fungi, without destruction of the organisms. Dr. Schreiner's account of the value of the enhanced suppression of growth of *Staphylococcus aureus* in cultures subjected to both penicillin and hyperbaric oxygen also deserves to be noted, since it raises the possibility of the combined use of antibiotics and hyperbaric oxygen in the treatment of infections due to a variety of different organisms as well as in those due to anaerobes.

The editor and publishers are to be congratulated on the clear presentation and arrangement of the individual contributions, which together serve as a very useful guide to the present status and possibilities of oxygen therapy in medical practice. A particularly valuable feature of the book is the inclusion of discussions relevant to particular communications, so that many different and often divergent views are presented on this important technique.

R. E. Coupland

BRAIN OF AN APE

A Stereotaxic Atlas of the Chimpanzee Brain (Pan satyrus)

By M. R. DeLucchi, B. J. Dennis and W. R. Adey. Pp. 155. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1965.) 15 dollars; 120*s*. net.

RELATIVELY few biologists can expect to count chimpanzees among their experimental animals; price and scarcity are but two of the factors against this. On the other hand, this animal, with its relatively large brain resembling, anatomically at any rate, that of the human being to a remarkable degree, clearly offers advantages for experimental neurological studies possessed by few other living creatures.

A Stereotaxic Atlas of the Chimpanzee Brain, produced by M. R. DeLucchi and his colleagues, is based on the brains of eight chimpanzees, four of either sex, aged from about one to five years. Inevitably, the dimensions of the skulls and brains of such a group of animals may vary appreciably, and the series is clearly too small to derive precise relationships between the two which would be readily applicable to any specimen. The authors, however, show a maximum variation in length and breadth of the brains of approximately 5 per cent from the mean, that is about 5 mm, and suggest that this is small enough to give essentially the same probability of encountering a given structure stereotaxically as in the brains of smaller primates, available in larger numbers for the production of such an atlas. Variability of this kind must in any event be accepted as a necessary shortcoming of data derived from limited amounts of material.

This *Atlas* consists essentially of sixty-nine enlarged line drawings taken from sections through the brain each accompanied by a photograph of a myelin-stained and a cell-stained section at the same level. Horsley Clarke reference planes are given both for drawings and photographs. The first thirty-four drawings depict sections cut in a frontal plane, extending from the rostral part of the basal ganglia caudally to a plane passing through the medulla at the level of the inferior olivary nucleus. These figures show in labelled detail only subcortical structures, but a small outline of the whole section is also given. The second half of the volume consists of thirty-five drawings taken from sagittal sections extending laterally from the midline to a plane passing

through the claustrum. In this series the whole brain is included in the figures and again Horsley-Clarke reference planes are given.

The general production of the volume is good. The main features of the photographs are labelled, while the line drawings carry a more detailed indication of the various structures. Quite apart from the primary object of the book, the reproductions of the myelin-stained sections make it a valuable *Atlas* for comparative neurologists. It would have been even more valuable had the photographs of the cell-stained preparations been of a higher standard, but the reproductions of the frontal series are too small, and in both series contrast is poor. With this reservation, however, the volume is a useful contribution to the field of comparative and experimental neurology.

R. L. HOLMES

TRIBAL SOCIETY AS SEEN FROM MANCHESTER

Politics, Law and Ritual in Tribal Society

By Prof. Max Gluckman. Pp. xxxii + 339 + 24 plates. (Oxford: Basil Blackwell, 1965.) 47*s*. 6*d*. net.

TRIBAL society in Prof. Gluckman's new book is by and large confined to tribal Africa. This in fact constitutes a source of strength. Prof. Gluckman's chief theoretical contributions concern African societies—and this enables him to evaluate authoritatively and advocate enthusiastically the contributions of his Africanist colleagues.

Politics, Law and Ritual in Tribal Society begins with a review of the mistakes and achievements of some of the anthropological ancestors and then develops the theoretical perspective of contemporary social anthropology. Next follows a chapter on the nature of property rights and economic activity in tribal societies. This provides a background picture for the later subject-matter of the book.

Chapters 3 and 4 are concerned with the analysis of political relations, a field in which Prof. Gluckman has made some of his best-known contributions. He elucidates the point that many societies portray conflict in their organizing principles, that in fact conflict is often an attribute of society itself. In regard to societies which have no governmental structures he explains how conflicts are contained by a network of social ties, "so that men who are opposed to each other under one rule, are allied with each other under another rule".

The next problem taken up concerns order in societies with formal authority systems, especially those which constitute states. Some years ago he propounded the thesis of the 'rebellious cycle' and 'repetitive equilibrium', the main idea being that South African polities were held together because their territorial segments fought for a common prize, the kingship, and that rebellions produced no changes in political form. Prof. Gluckman has since advocated this thesis with decreasing conviction and increasing delimitation of the societies and time periods to which it may be applicable. In this book he describes how many or most states have frequently fragmented for many reasons, and puts forward an idea which he describes as 'akin' to that of Edmund Leach's (concerning Upper Burma) that regions of Africa have oscillated between large states and numerous small states. It may well be accepted in the future that concepts like repetitive equilibrium are rarely adequate abstractions of the actual dynamic facts.

The discussion of "Dispute and Settlement" (Chapter 5) is admittedly polemical. Prof. Gluckman demonstrates with admirable forensic skill that the forms in which disputes are expressed and the varied procedures adopted for resolving them make sociological sense only when they are related to the ranges of social relationships within which they operate. He introduces many concepts to distinguish between various kinds of dispute procedures and roles; perhaps not everyone, however, will share his enthusiasm that "specializing of the use of words out of the riches of English" will clarify our theoretical problems.

Prof. Gluckman's treatment of "Mystical Disturbance and Ritual Adjustment" (Chapter 6) is a disappointment. Following the Neo-Tylorian intellectualists, he distinguishes between 'mystical beliefs' and 'empirical beliefs', a distinction which the Western observer cannot easily make, let alone the primitive. The disappointment is not that he has made such a distinction, but that, having defined ritual in relation to mystical beliefs, he interprets it entirely in terms of its social effects. This reductionism has no bearing on the initial definition and distinctions made between ritual and ceremonial.

Furthermore, in the space of one chapter, he advances several disconnected views of ritual. The mystical definition of ritual has little bearing on the submission that ritual segregates roles and changes of roles and activities in small-scale societies with multiplex relations. Another avenue is explored when, following Victor Turner, he postulates the conditions under which judicial as opposed to ritual techniques for resolving social conflict may occur. Thus certain rituals are said to cloak fundamental disharmonies which arise out of conflicts of social principles. Turner made sense of Ndembu rituals of affliction in these terms; in trying to assimilate Turner's views to his own, Prof. Gluckman fails to achieve a marriage of ideas, for his own theory of 'rituals of rebellion' is of a different kind and tailored to fit different ethnographic facts. Finally, despite his own claims, Prof. Gluckman has not taken us any further in understanding why, in tribal societies, misfortunes are associated with the moral relations of the group concerned, why rituals which 'state conflict' indeed 'bless the moral order and its related natural order'.

A major theme that runs through the book is the developmental morphology of economic and political systems. This is dangerous ground to tread on and Prof. Gluckman once again demonstrates this. He works with an evolutionary scheme (the notion of two social types and transition from one to the other) which harks back to Maine, Durkheim, Toennies and others. Anthropologists have found such grand schemes of change descriptively true in a general sense but in practice too diffuse to explain the particular problems that engaged their attention. Prof. Gluckman's hypotheses show the same limitations. He explains the wide extension of kinship in tribal society as due to their undifferentiated economy, and its shrinkage to the differentiation in developed industrial society. But how does this formula help to account for the wide variations in kinship systems in tribal societies? How does the notion of tribal economy illuminate the widespread systems of ceremonial and economic exchange in, say, Melanesia which differ markedly from the African situation? Another hypothesis which stems from his morphological series is that rituals of rebellion (or 'role revealing rituals') associated with a particular kind of political and economic situation will be replaced by temple cults in more developed states where the existing structure of society is not accepted as hallowed. This is untenable, as a reference to temple cults in India and Ceylon will show, and is based on the misapprehension that temple cults lack "ritualisation of secular roles".

Prof. Gluckman has presented his book to the general reader as a statement "of how one social anthropologist, working in the full tradition of the subject, sees the general problem of rule and disorder in social life". Other anthropologists who also feel themselves to be in this full tradition may see certain questions differently, for this tradition is fuller and less consistent than he indicates.

S. J. TAMBIAH

Science and the Politician

By Marcus Goodall. Pp. viii+83. (Cambridge, Mass.: Schenkman Publishing Company, Inc., 1965.) 2.65 dollars.

CONCERN as to the extent of the possibility of planning human activities is shown both by those who welcome the increase of regulation and those who deplore it. Neither party is prepared to consider that the dispute should be subject to investigation; that we should study the extent to which planning is likely to be effective, given the means available at any time.

This is only one practical example of the type of study that Dr. Goodall calls "third science". It is characterized by attention to aims and yet by recognition of the problems that are involved in defining aims. In such respects it transcends the 'second science' of Newton, Maxwell and Einstein, which required drastic uniformizing assumptions, such as those that limit the applicability of the Second Law of Thermodynamics.

Goodall traces the beginning of the modern period back first to Darwin, then to Pierce, with his emphasis on the relationship of observer, symbol and object, and from here to Cantor, Gödel and Tarski. The connexions are only sketched out, but the effect is to provide a series of hints as to the logical problems underlying modern science and especially biology.

The book is especially concerned to point out the inadequate use that is made of modern scientific and logical possibilities by those concerned to regulate the conduct of modern affairs (and particularly 'politicians', the author's favourite aunt-sally). In this, it well represents the frustration that many feel, who see so little use made of such powerful methods. The special value of methods such as those of specification theory, games theory and the like is that it should be possible with them to suggest means to further their wider adoption for human ends. It is to be hoped that Dr. Goodall will follow this stimulating essay with more detailed proposals in which such methods are used to assess the best strategy for applying them.

J. Z. Young

Elementary General Topology

By T. O. Moore. Pp. xi+174. (Englewood Cliffs, New Jersey, and London: Prentice-Hall International, 1964.) 48*s*.

THIS very readable book provides an introductory account of general topology (but not algebraic topology) for the beginner. There is some doubt as to when topology should first appear in the training of a mathematician; but the author of this book, after several years' experience in teaching topology to undergraduate and post-graduate students, came to the conclusion that an introductory course might best follow a prior course in abstract algebra, and precede the study of advanced calculus and real analysis. Thereby, it is claimed, "maximum results follow minimum effort". So the present book has been written primarily as a text for undergraduates.

The first chapter is concerned with elementary set theory. Then follow chapters on topological spaces, mappings of such spaces, and compactness. After that, there is a general development of the properties of product spaces, metric spaces and function spaces. An important chapter, on nets and convergence, is concerned mainly with the generalization of the idea of convergence of a sequence to a point in a space. The book closes with a chapter on Peano spaces (continuous curves).

In a book of this kind there are necessarily many definitions. These are clearly stated, often illustrated, and the theorems are separated by graded exercises. At the end of each chapter there is a list of miscellaneous exercises, and, all in all, the book should appeal to students looking for a text supplementary to a course of lectures on the subject.

L. S. Goddard

Supplemental Tables of Molecular Orbital Calculations

By Prof. A. Streitwieser, Jr., and Prof. J. I. Brauman. With a Dictionary of π-Electron Calculations by Prof. C. A. Coulson and Prof. A. Streitwieser, Jr. Vol. 1: Pp. xxiv+1–860. Vol. 2: Pp. 861–1223+xxx+358. (London and New York: Pergamon Press, Ltd., 1965.) £33 net per set.

HÜCKEL calculations are now a matter of pure routine, but this does not detract from their value as a guide to the physical and chemical properties of conjugated molecules; indeed, in spite of heavy competition the Hückel theory remains the best wave-mechanical model of molecules that we have.

Supplemental Tables of Molecular Orbital Calculations presents the results of Hückel molecular orbital calculations on almost 500 hydrocarbons. The calculations have been performed on a digital computer and the output of the computer has been photographed so that the published papers are free from any errors of transcription. This makes the tables particularly reliable for use by people who do not have the necessary skill to programme molecular orbital calculations themselves. The printed results include the energies and coefficients of all the molecular orbitals of the molecules considered, their total π energies, electron densities and bond orders, and the various types of mutual polarizability. The introduction explains the tables and shows how they may be used. Volume 2 includes the "Dictionary of π-Electron Calculations" which is used also as a separate volume.

The compilation of this considerable body of data is likely to be most useful to the chemist who does not possess access to a computer; the price of the volumes, though relatively high, is negligible compared with the cost of the computing time and expertise which would be needed to carry out a calculation on a mere handful of the molecules treated.

H. C. Longuet-Higgins

Freshwater Microscopy

By W. J. Garnett. Second, revised edition. Pp. xv+376+54 plates. (London: Constable and Co., Ltd., 1965.) 42*s*. net.

THIS edition of *Freshwater Microscopy* is a great improvement on the original. The inclusion of more information, twenty-six excellent new figures and four new plates, and the bringing up to date of techniques and bibliography, all contribute to this. Apart from the slight expansion of certain paragraphs and the introduction of common species omitted from the first edition, eight of the fifteen original chapters remain substantially unaltered. Of the other seven, the chapter on microscopic equipment has been rearranged in parts to embrace modern methods and equipment, and the chapters on bacteria and fungi, the higher plants and molluscs have been rewritten and enlarged. Leeches have been gratifyingly included in the chapter on worms. The arthropods are now allocated three chapters instead of two, due mainly to the introduction of many more insect species.

While scientific inaccuracies are rare, a few do occur. For example, a single cocoon occurs in *Microdalyellia* and not *Dalyellia*; there are fourteen, not thirteen British species of leeches; leeches can have up to ten eye-spots—not up to eight; *Planorbis spiralis* should be *P. spirorbis*; and *Holopedius gibbeus* should be *Holopedium gibberum*. Though the bibliography has been extended and brought up to date, there are still obvious omissions such as "A Guide to Freshwater Invertebrate Animals" by T. T. Macan, and two recent publications on mayflies and oligochaetes in the Freshwater Biological Association series. The exclusion of the publisher and on occasion the date of publication is still rather irksome.

These are, however, but minor criticisms of an enhanced edition which admirably fulfils its purpose to "set the beginner . . . on the right path".

J. O. Young

THE DISTINCTIVENESS OF *Homo habilis*

ROBINSON[1] has questioned the validity of the new species, *Homo habilis*, proposed by Leakey, Tobias and Napier[2]. In particular, he has adduced evidence purporting to invalidate the morphological criteria which, it has been claimed, differentiate *H. habilis* from *Australopithecus*. Since Robinson's paper, at first reading, may give the impression that our claim for the existence of differences has been effectively demolished, it is necessary to look into the claimed differences more deeply.

The Dental Traits

In our diagnosis of the features of *H. habilis*, we stated that among the dental traits is "a marked tendency toward buccolingual narrowing and mesiodistal elongation of all the teeth, which is especially evident in the lower premolars . . . and in the lower molars"[2]. We maintained —and still maintain—that the lower premolars are absolutely narrower than those of *Australopithecus*

Robinson[1] regards the shape characteristics of the *H. habilis* teeth as not recognizably different from those of the australopithecines. The data on which he bases his conclusion are open to two criticisms. First, Table 1 in his paper, which shows the length/breadth indices of some of the cheek-teeth, inexplicably excludes the fourth premolar (P_4) although we had been at pains to point out that the premolars exhibit the greatest departures from the australopithecine teeth.

Secondly, the figures quoted by Robinson[1] for P_3 of *A. robustus* (*Paranthropus*) differ substantially from those quoted in his dental monograph of 1956 (ref. 3). In the earlier work, he lists the *M–D* length and *B–L* breadth of 12 Swartkrans "first premolars"; these include one tooth—*SK* 96—the measurements of which are marked with an asterisk. He then states in the text "the results of *SK* 96 have not been used in calculations because of incomplete development of the crown" (*op. cit.*, p. 69). I have therefore calculated the length/breadth indices of the other eleven P_3's and find they range from 76·0 to 92·8, with a mean of 83·25. The figures quoted by Robinson in his 1965 table for *Paranthropus*, however, present a range more than twice as great, that is, from 76·0 to 112·3. Robinson has apparently included in his latest range the incompletely developed tooth *SK* 96. For, as he states[1], the sample size for this tooth now is 12, not 11. Moreover, he explains his inclusion of the tooth *SK* 96 as follows: "The highest value listed for *Paranthropus* belongs to a tooth which had not yet begun to erupt and the final dimensions would possibly have been slightly higher than at present, although the length dimension already is very close to the upper limit for the sample of 12 specimens".

The length of *SK* 96 as recorded by Robinson[3], that is, 10·1, is indeed near the top of the range for the other eleven P_3's from Swartkrans, that is, 9·2–10·5. However, its breadth is only 9·0, which is well below the smallest value in the range of the other eleven teeth, namely, 10·6–12·9. In his earlier investigation (p. 70) he pointed out: "In *SK* 96 (incompletely developed crown) the lingual face is not strongly convex and a distal lingual groove is present. Neither of these features occurs in any of the fully developed and erupted teeth. Furthermore this tooth is appreciably narrower than any of the others. Presumably all these features are a result of incomplete development".

Elsewhere (p. 78) he calls this tooth "an incompletely developed germ". Recently, therefore, I have re-examined the original specimen in the Transvaal Museum, Pretoria, through the courtesy of Dr. V. FitzSimons and Dr. C. K. Brain. The tooth is clearly immature and its measurements cannot validly be included. At the time of death, the tooth was completely enclosed in its crypt, the most superficial part of the lamina dura being as much as 9·5 mm below the alveolar margin. The roots of the overlying dm_1 are in position and there is no evidence that resorption has begun; the whole of the distal root is visible and it is intact down to its exposed apex. When the P_3 is replaced in its correct position (indicated by part of the lamina dura and lateral mandibular wall adherent to it), there is a moderate space between the occlusal surface and lamina dura for the enamel organ, and a large space below the crown for the tooth-germ or pulp. Clearly, this tooth was far from erupting. The crown enamel is pale and highly translucent, unlike that of mature teeth from the same site. Obviously, much more enamel would have been added before the tooth had erupted. A further relevant observation was made: the crown of the tooth has been fractured and repaired; the alignment of the two moieties is not perfect, thus fractionally increasing the apparent length.

The measurements made on this developing tooth and the derived *L/B* index are thus not eligible for inclusion in the range of measures of mature teeth available for comparison. Nor is Robinson's assumption justifiable that "it is highly improbable that any slight increase in the crown dimensions [of *SK* 96] that may have occurred before eruption would alter the shape so disproportionately as to change the shape index significantly". The indices of twenty-three fully formed and erupted australopithecine P_3's from six sites range from 68·1 to 92·8; the *SK* 96 value of 112·3 suggests most strongly that if this tooth is a normal member of the same group, further development would yield a greater breadth and consequently a lower length/breadth index.

It is largely through including this immature P_3, *SK* 96, and excluding the P_4 that Robinson has provided the semblance of refuting our statements about the differences between *H. habilis* teeth and those of the australopithecines. When these errors of omission and commission are rectified, our statements remain valid.

Habiline Dental Evidence and Comparative Data

To demonstrate further the relationship between the absolute and relative dimensions of the *H. habilis* teeth and those of *Australopithecus*, I have compiled all available maxillary and mandibular dental measurements and indices on the specimens from Sterkfontein, Makapansgat, Taung, Swartkrans, Kromdraai, Garusi, Olduvai and Peninj. Many of these measurements are culled directly from Robinson's outstanding monograph[3]; others have been taken from Dart[4]; while I have personally measured a number of additional teeth from Sterkfontein, Kromdraai and Makapansgat, and all the available australopithecine teeth from Olduvai and Peninj. Data have been compiled for 23 australopithecine P_3, 22 P_4, 33 M_1, 26 M_2 and 28 M_3. Of the front teeth, there are data for 10 I_1, 8 I_2 and 20 C. Corresponding figures for maxillary teeth are 12 I^1, 15 I^2, 25 C, 38 P^3, 33 P^4, 33 M^1, 33 M^2 and 30 M^3. These figures are cited to give some idea of the

splendid samples of australopithecine teeth available for comparison. The data provided by these large samples formed the background for our statements about the divergence of *H. habilis* teeth from those of the Australopithecinae.

Similarly, I have compiled comparative tables of absolute measurements and of indices for some 136 mandibular and 66 maxillary teeth of *H. erectus* (including *Pithecanthropus, Sinanthropus, Atlanthropus, Telanthropus*, Mauer and Montmaurin). It is worthy of note that (*a*) the samples of *H. erectus* permanent teeth available are smaller than those of *Australopithecus* (170 mandibular, 219 maxillary), and (*b*) the relative numbers of upper and lower teeth discovered are reversed.

All the measurements of australopithecine and hominine teeth made by myself, including those made with von Koenigswald on original Javanese and Chinese teeth[6], were carried out with a specially prepared pair of Vernier callipers, having delicately tapering points for insertion between teeth in jaws. The technique used is considered to be comparable with that of Robinson, since numbers of his recorded dental measurements have been confirmed on the same specimens, to within a maximum margin of 0·3 mm, but a mean margin of about 0·1 mm. Each Olduvai tooth has been measured at least twice, and some thrice, by the same observer but at different times, generally with a lapse of at least 1 year between two of the measurings. Fluctuations have been small, most commonly of the order of 0·0–0·2 mm. Where successive measurements of the same dimensions differed, the mean of the two readings has been calculated and used.

In Tables 1 and 2, the mesiodistal lengths and the buccolingual breadths of the australopithecine and *H. habilis* teeth are presented. Only the *H. habilis* type and paratypes from Bed I are included, since we now consider the Bed II hominine to belong to a more advanced form[5].

The total morphological pattern of the *H. habilis* teeth obviously aligns them more closely with those of *A. africanus*. The metrical differences from the latter are therefore of most value in determining whether or not the habiline teeth belong to a different taxon. However, for the sake of completeness, we have included the dimensions of the *A. robustus* and *A. boisei* teeth.

In absolute length, only the habiline P_4's exceed the sample of 5 *A. africanus* P_4's, but in absolute breadth, both P_3 and P_4 are narrower than the entire samples of 23 P_3's and 22 P_4's. The absolute narrowing tendency of the *H. habilis* teeth is seen as well, though not so markedly, in the molars: the breadths of M_2 and M_3 lie near the bottom of the ranges for *A. africanus*, while of 33 australopithecine M_1's, only one specimen from Sterkfontein and one from Kromdraai are definitely narrower than those of *H. habilis*.

Thus, considering not merely the single type-specimen of *H. habilis*, but the whole group of mandibular teeth representing at least three different individuals from three different levels in Bed I (*MK*, *FLKNN* and *FLK* from below upwards), we may reasonably conclude that the group was characterized by absolute lengthening of P_4 and a tendency towards absolute narrowing of all the cheek-teeth, especially the premolars.

Table 3 shows that, when the 'relative' narrowing of the *H. habilis* teeth is gauged by the length/breadth index, all the *H. habilis* cheek-teeth have indices at, or above, the top of the range for *A. africanus*. The indices derived from Robinson's measurements on the type specimen, as quoted in his 1965 paper[1], emphasize this even more strikingly than those from my own measurements, for P_3 and M_1. Teeth from all individuals of

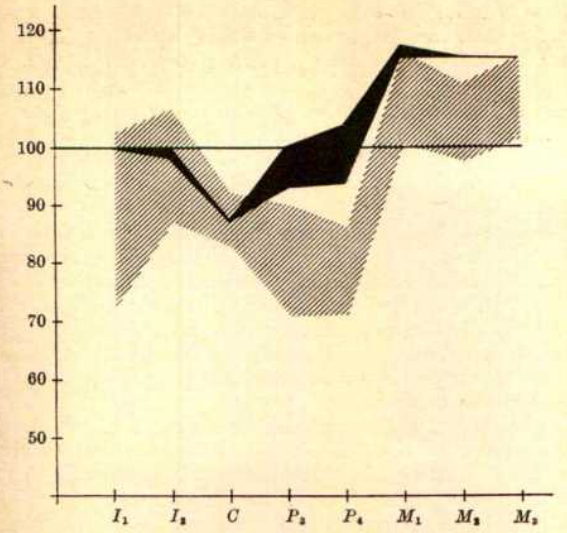

Fig. 1. Ranges of variation in the length/breadth indices of mandibular teeth of *Homo habilis* (black area) from Bed I, Olduvai Gorge, and of *Australopithecus africanus* (hatched area)

H. habilis agree in showing a high index. Table 3 provides unequivocal verification that the Bed I habilines were characterized over an extended period of time by relatively narrower teeth than were the members of *A. africanus* or of the Australopithecinae in general.

Naturally, the small sample of Bed I habilines can give but a poor picture of the variability of *H. habilis*, yet the clustering of three individuals to one side of the bigger australopithecine sample positively suggests the existence there of a population the mean dental shape of which was different from that of *A. africanus*. The mean indices for *H. habilis* and *A. africanus* confirm the differing tendencies in the two groups (Table 3), as do the graphs of the ranges (Fig. 1).

Similarly an isolated upper M^1 from the *H. habilis* type-site has a length/breadth index (102·3) which falls beyond the top of the range for 15 *A. africanus* M^1's, namely, 86·5–97·7. Another upper molar comes from the *A. boisei* type-site and its index (106·5) shows an elongate shape matched only by that of a single well-worn Makapansgat M^2 (*MLD* 24) with an estimated 107·1, while thirty other *A. africanus* upper first and second molars range from 83·1 to 97·7. Clearly, these two upper teeth from two different levels in Bed I—and which may or may not belong to the same individuals as those represented by the lower teeth from those sites—confirm the presence of the narrowing tendency in the maxillary teeth of some Bed I hominids.

The incisors likewise show a strong tendency to absolute and relative mesiodistal elongation and labiolingual narrowing. In *L/B* index, I_1 and I_2 fall at the top of the ranges for ten australopithecine I_1's and eight I_2's respectively, while I^2 greatly exceeds the top of the range for thirteen australopithecine I^2's.

Inner Contour of Mandible

The photographic reconstructions, which Hughes and I made a few years ago of the *H. habilis* type mandible, do not bear out Robinson's claim that the latter has a typically australopithecine internal mandibular contour. Marked differences are present (Fig. 2), especially when the type mandible is compared with the Makapansgat juvenile mandible which belonged to a youth of almost the same individual age.

Fig. 2. Reconstruction of the type mandible of *Homo habilis* (left) compared with the juvenile mandible (*MLD* 2) from Makapansgat, belonging to an individual of approximately the same age

The 'Phyletic Valence' of the *L/B* Index

What Robinson calls "a far more trenchant criticism" of our use of the *L/B* index is his assertion that this index is of "extremely low phyletic valence", so far as hominids are concerned. As examples, he cites his figures for one tooth, namely, P_3: but each hominid group cited by him is based on only one or at most two sites. Thus, his *H. erectus* sample is confined to the Choukoutien teeth and his

* Worn tooth.
† Two sets of indices are given for most of the type specimen's teeth, those of Dr. Robinson (J.T.R.) and those of the author (P.V.T.).

Paranthropus sample largely to the Swartkrans teeth. Conclusions about the ability of the *L/B* index to distinguish between these taxa must necessarily be based on the larger and geographically more diverse samples now available. The data I have compiled for comparison with the habiline teeth include measurements and indices for 22 *H. erectus* P_3's from no fewer than seven sites in three continents (as against thirteen from Choukoutien alone); similarly twenty-three M_1 (as against eleven) and eighteen M_2 (as against seven). Table 3 shows that, while *L/B* scarcely differentiates between *A. africanus* and *A. robustus/boisei* for P_3, M_1 and M_2, it does yield differing means for P_4 (79·2, 85·7) and for M_3 (109·4, 115·9), the two mandibular cheek-teeth omitted from Robinson's Table 1. Moreover, there are marked differences of the means between *H. habilis* and *A. africanus* for all five mandibular cheek-teeth. These figures indicate that the *L/B* index is more useful in distinguishing among lower Pleistocene hominids than Robinson believes.

Apart from these details, however, the very basis of Robinson's view is unacceptable. The taxonomic usefulness of a character in any specific comparison depends on its ability to differentiate between the two taxa considered. The fact that the *L/B* index fails to distinguish between certain teeth of *A. robustus* and *A. africanus* in no way lessens, in fact enhances, its usefulness as a mark of distinction between *H. habilis* and *A. africanus*. It is totally irrelevant to this latter comparison that some teeth of some other groups do not differ in *L/B* index. The vital fact remains that this index does show a definite difference between *H. habilis* and *A. africanus*. In our description of the type specimen, this was clearly a metrical difference to be included, in accordance with Art. 13 *a* (i) of the International Code of Zoological Nomenclature, which lays down that a new species name must be "accompanied by a statement that purports to give characters differentiating the taxon". *L/B* is one such character, which differentiates the taxon *habilis*, irrespective of whether the same character can as effectively differentiate other taxa.

The Cranial Capacity of *Homo habilis*

Robinson states: "The endocranial capacity of *H. 'habilis'* appears, on the scanty and indirect evidence available, to have differed little from that of the australopithecines with a range overlapping that of the latter substantially" (*op. cit.*, p. 122).

Let us re-examine that evidence. Associated with the type-specimen were large parts of two beautifully preserved and undistorted parietal bones. They were patently bigger than the parietal bones of any australopithecine yet discovered. The sagittal arc from bregma to lambda measures 105 mm, whereas those of five australopithecines range from 74·5 to 91·5. The lambdoid arc from pterion to asterion is 69·0 in *H. habilis*, but ranges from 55·5 to 62·5 in australopithecines. The coronal edge, although not perfectly preserved, likewise exceeds the top of the australopithecine range. Such large parietals necessarily covered a larger brain than that of any australopithecine known hitherto.

That fact was clearly acknowledged by Robinson in 1962[6]. There he endeavoured to show that early stone tools were not made by *Australopithecus*. In that investigation, he explicitly included 'pre-Zinj' (that is, the type specimen of *H. habilis*) as a larger-brained contemporary of *Australopithecus*. Thus he stated: "In fact, there is evidence throughout the entire australopithecine period either proving or suggesting the presence of a more advanced form of hominid. There are the large parietals in the 'pre-Zinj' level of Olduvai, *'Telanthropus'* at Swartkrans associated directly with *Paranthropus*, and at Sangiran *'Pithecanthropus'* and *'Meganthropus'* occur in association" (*op. cit.*, p. 102).

It was a logical and imperative step after measuring the parietals to estimate the cranial capacity. This was done[7] by using a biparietal partial endocast as a basis. The method provided a precision unattained in the wide range of estimated figures previously published for the australopithecines[8,9]. The central value (680) of the range of estimates for *H. habilis* (643–724) is about mid-way between the capacity of the biggest-brained australopithecine (562) (ref. 10) and that of the smallest-brained *H. erectus* (775). Furthermore, it is a fair inference that, had the type individual of *H. habilis* grown to adulthood, his cranial capacity would have been somewhat larger than the capacity estimated. Surely it is as valid to infer that the population range in *H. habilis* would overlap appreciably that of *H. erectus*, as to emphasize (as Robinson[1] prefers) its equally likely overlap with that of *Australopithecus*.

Hence the habiline remains, both in their dental departures and their brain-size, as well as in their inferred stone tool-making activities[11], form a population intermediate between *A. africanus* and *H. erectus*.

Where opinions may validly diverge is in the weight laid on these differences. When all presently available evidence is taken into account, we feel justified in concluding that (i) the habiline population represents a distinct taxon; (ii) this habiline taxon is more closely related to the hominines than to the australopithecines and should be placed in the genus *Homo*.

Further specimens could alter this point of view: they may spread the habiline range more towards the australopithecines or more towards the hominines, or both. In the former event, there would be no hesitation in reconsidering the classificatory position of *H. habilis*, but on present evidence a taxonomic re-alignment would seem premature. In much the same way, Mayr[12], who demoted *Australopithecus* from separate generic status in 1950 to place it under *Homo* as a *transvaalensis* species, has recently reinstated it as a separate genus[13].

Whatever designation taxonomists may finally adopt, the view I expressed at the seventh International Congress of Anthropologists and Ethnologists, in Moscow in August 1964 (ref. 11), was that the Bed I *habilis* fossils represent a form intermediate between *A. africanus* and *H. erectus*. This view is acceptable to many workers, including apparently Robinson[1]. Furthermore, the anatomical features of the Bed II hominines and *H. habilis* permit one to envisage at least a part of the habiline population of Bed I times moving forward to become the hominines of Bed II times. These phylogenetic implications of the new discoveries have been fully discussed elsewhere[14,15].

Whether recognition of an evolutionary stream from *A. africanus* → *H. habilis* → *H. erectus* justifies putting all these taxa under *Homo*, and separating them generically from *Paranthropus*, as Robinson suggests, is another matter entirely. To effect this re-alignment he relies perforce on phylogeny and ethology (implemental activities). Phylogeny and ethology may be valid sources of taxonomic inference, but it would be an unusual practice to allow them to outweigh inferences from morphology. Morphologically *A. africanus* and *A. (Paranthropus) robustus* have so much in common, that several recent international symposia on the taxonomy of fossil hominids, one at Burg Wartenstein in 1963 (ref. 16) and one at Moscow in 1964, were virtually unanimous in recognizing these two taxa as separate species of the one genus *Australopithecus*. As Mayr[13] has pointed out, the morphological differences between *Paranthropus* and *A. africanus* "are no greater than among species in other groups of mammals". My studies of the South African australopithecines, in comparison with *A. (Zinjanthropus boisei*, demonstrate more extensive areas of morphological overlap between these two South African forms than have as yet been commonly recognized. To lump *A. africanus* under *Homo*, and retain *A. robustus* in *Paran*

thropus, would be tantamount to saying that there is less difference between *A. africanus* and *H. erectus* (or even *H. sapiens*) than between *A. africanus* and *A. robustus*.

The australopithecines clearly represent a single grade of hominid organization. The group is highly variable and we may so far recognize a mesodont branch (*A. africanus*), a macrodont branch (*A. robustus*) and a megadont variant (*A. boisei*). Already it is known that these three forms show a large measure of overlap, only a few features, such as the canine/*P*3 ratio and the *P*3/*P*4 ratio, showing an absolute distinction between them. The fact that one of the three forms may bear a phyletic relationship to *Homo* is no reason to remove it from the genus *Australopithecus* and place it in *Homo*. On the other hand, *habilis* is a more advanced hominid than any of the members of the *Australopithecus* group. In fact, in teeth and jaws, it is certainly more hominized than *Meganthropus*, which in turn von Koenigswald and I believe is more hominized than the australopithecines, while neither Weidenreich[17] nor Le Gros Clark[18] could separate *Meganthropus* generically from *Pithecanthropus* (*H. erectus*), a view which Schultz[19] is also inclined to support. If further discoveries of skull, dentition and limb-bones attributable to *Meganthropus* confirm that it is not separable from *H. erectus* at generic or specific level, then *habilis* would be even more emphatically a hominine than we have claimed—and we should have to call it *Homo erectus habilis*—as D. R. Hughes[20] and Ashley Montagu[21] have already suggested. Meantime, it would be safer to continue to regard *habilis* as a species within *Homo*, thus avoiding the extreme taxonomic evaluations on either side of this middle-of-the-road position.

I thank Dr. and Mrs. L. S. B. Leakey, Prof. R. A. Dart, Mr. A. R. Hughes, Miss J. Soussi and Mrs. R. W. Levine for advice and help. I thank the South African C.S.I.R., the Boise Fund, the Wenner-Gren Foundation for Anthropological Research and the University of the Witwatersrand for financial assistance.

In his comments on my views on the validity of the supposed taxon *H. habilis*, Tobias exhibits misapprehension of the basis of my criticism as well as confusion over some basic principles of taxonomy.

The existence of some detectable differences between the known specimens attributed to *H. habilis* and the known australopithecine material is not disputed. The point at issue is the significance of those differences.

Tobias believes that I am mistaken in thinking that the internal mandibular contour of the type specimen of *H. habilis* is of the australopithecine, not the hominine, type and provides his Fig. 2 to prove this. However, this illustration fully supports my view and disproves his. The nature of the internal mandibular contour is a character which, to the best of my knowledge, was introduced into the literature by me and I have always used it in the same way. In australopithecines the space enclosed by the internal contour of the corpus mandibulae, when seen in occlusal view, is relatively narrow, narrows rapidly as the symphysis is approached and, at the level of the P_4–M_1 contact, is narrower than the corpus thickness at this level. On the other hand, the hominine condition is one in which the internal contour is wider, does not narrow rapidly forwards and, at the level of the P_4–M_1 contact, is appreciably wider than the corpus is thick in that position. Fig. 2 of Tobias shows both the *H. habilis* and the *Australopithecus* mandibles with the same robust corpus and narrowing V-shaped contour that I have described for australopithecines. The wide U-shaped contour and more gracile corpus that I have described for hominines does not occur in either of these specimens. This is demonstrated in Fig. 1 which I have prepared. It is therefore clear that the *H. habilis* type mandible is indeed of the typical australopithecine sort with respect to this character complex.

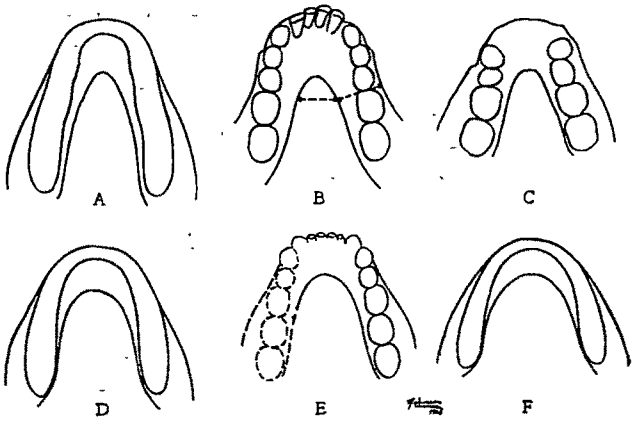

Fig. 1. Diagrammatic representation of the internal mandibular contour of: *A*, adult *Australopithecus* (*sensu stricto*) from Sterkfontein; *B*, adolescent *H. habilis* type from Bed I, Olduvai; *C*, adolescent *Australopithecus* from Makapansgat; *D*, adult *H. erectus* (equals *Telanthropus*) from Swartkrans; *E*, adult *H. habilis* from Bed II, Olduvai; and *F*, adult modern *H. sapiens*. The specimen in *E* has suffered slight damage on the left side; this has been allowed for by reflecting the right side, though most of the internal contour is undisturbed and only the portion indicated by a broken line is taken from the right side. The relevant dimensions for this character are indicated in *B*. *B* and *C* have been drawn from Fig. 2 provided by Tobias in his accompanying communication; *E* has been drawn from published photographs[4,5]

Tobias makes the explicit claim that his estimate of the endocranial volume of the skull from which the two incomplete parietals from Olduvai Bed I came represents "a precision unattained in the wide range of estimated figures previously published for the australopithecines". The best previously published estimate was that for *Sts* 5 from Sterkfontein; a skull which is almost complete and has the braincase virtually intact and apparently undistorted and empty, so that the endocranial volume can be measured directly by conventional methods. As I see it, therefore, Tobias is claiming that he can make a more accurate estimate of endocranial volume on the basis of two isolated and incomplete parietals than Broom and I could by conventional methods on a complete skull.

The difference between the passage quoted by Tobias and my later statement that the apparently greater volume of the *H. habilis* specimen does not necessarily indicate difference from *Australopithecus* (*sensu stricto*) is easily explained. Some time after writing the first statement I had occasion to re-investigate the evidence relating to cranial capacity in the australopithecines. I found that six estimates were possible for *Australopithecus* (*sensu stricto*): two very good ones and four of lesser reliability,

but based on more than parietals alone. From these estimates the probable range of variation in the population was calculated. The mean was 430 cm³ and the range, using limits of 2·5 times the standard deviation on either side of the mean, was 300–550 cm³. On comparing these figures with similar ones calculated for pongids and modern man from data, based on substantial samples, provided by Ashton and Spence[1], it became obvious to me that even limits of three times the standard deviation seriously underestimate the upper limit of the observed range for both the gorilla and man. This being the case, it is possible that the *Australopithecus* range could similarly be underestimated. Using the percentage underestimate for man as a basis for adjustment, a corrected upper value of 680 cm³ was obtained and one of just more than 600 cm³ on the basis of the gorilla discrepancy. Since the former value coincides with the estimate obtained by Tobias for a single *H. habilis* specimen, it seems to me that it is no longer by any means certain that this value is significantly larger than could be expected from *Australopithecus* (*sensu stricto*) as represented by the South African specimens. Furthermore, since there is evidence that *Australopithecus* had already embarked on the hominine type of brain expansion, though *Paranthropus* apparently had not, the possibility of finding evolutionarily slightly later forms of the former with larger brains than are now known from South Africa must be reckoned with. It therefore seems to me that a single estimate of 680 cm³ for *H. habilis*, obtained on the basis of two incomplete parietal bones alone, is narrow support for the view that the latter is not merely specifically, but actually generically, distinct from *Australopithecus*.

I do not understand Tobias's charge that my views on hominid taxonomy are a consequence of using the 'unusual practice' of allowing phylogenetic and ethological evidence to outweigh morphological evidence. This charge involves a most thorough-going confusion concerning how phylogenetic conclusions are arrived at, the use of sorting criteria in setting up the original categories into which specimens are placed and taxonomic procedure in general.

When a varied collection of fossils is being investigated for the first time, it is sorted out into groups so that finally each group includes specimens of a single species. This sorting is done on the basis of morphological criteria and in the case of fossils there are no other sorts of criteria available. Any later conclusions regarding the species, genera or other taxa which may be reached and any phylogenetic conclusions arrived at are obviously ultimately based on the sorting criteria originally used to assemble individual specimens into species groups. Since no taxon is valid unless it includes, or is included by, at least one species, no matter what level the taxon occupies in the taxonomic hierarchy, it is clear that in the long run the entire hierarchy of classification depends on the sorting criteria used to sort into species the raw material of classification, the samples obtained from Nature.

It should be clear from my papers that, for example, my separation of *Australopithecus* and *Paranthropus* into distinct genera is based fairly and squarely on morphological evidence and on inferences which are similarly based, for example, on the nature of the masticatory apparatus, but related to ecological and behavioural aspects of the genera concerned. Even the cultural aspects involved can be said to be based on morphological evidence since they concern morphology on one hand, for example, of the hand and locomotor apparatus, and on the other structural features of physical objects (artefacts) found in the deposits with the specimens.

Secondly, in so far as Tobias considers, as his comment implies, that morphology is always a more valid basis for taxonomic conclusions than is any other sort of evidence, he is, I believe, mistaken. What makes and keeps one species separate from another in Nature is not just its morphology. Similarly, the fields in which we may look for evidence of similarity, hence of probable common ancestry, are by no means confined to comparative anatomy. Clearly the entire biology of the taxa concerned is involved, and surely physiology, behaviour and ecology are as much a part of an animal's biology as is its anatomy. Any of these can provide as effective a barrier for preserving the integrity of a species as morphology can. Usually morphology provides a more practical basis for distinguishing species because of the way in which taxonomic work is normally carried out. This does not mean it is a more valid basis for taxonomic conclusions, nor is morphology always the most practical means of sorting species. This is clearly demonstrated by some examples of sibling species where behaviour provides the best criterion for distinguishing them.

I believe that Tobias is mistaken in asserting that recognition of the series *Australopithecus—H. habilis—H. erectus* as a single phyletic sequence is the basis for my suggestion that perhaps *Australopithecus* should be included in *Homo*. The main basis of this suggestion is clearly stated in the final sentence of my paper: "In this event the whole lineage in which culture is a very important adaptive mechanism is included in a single genus . . .". In other words, the genus is here based on a clearly defined adaptation which distinguishes its members from those of all other genera. This adaptation involves a complex of morphological (for example, hand, brain and locomotor), behavioural (for example, tool-making, language and hunting) and ecological (for example, diet, subsistence pattern) elements forming one of the most clearly defined and powerful adaptations in the animal kingdom. I also pointed out that the sequence appears to contain no major morphological changes, no major shifts in evolutionary direction and did not occupy a very long geological time. On the other hand, as *H. habilis* is set up in the present taxonomic definition[2], it is not easily distinguished from *Australopithecus* at the generic level or *H. erectus* at the species level.

Tobias explains that lumping *Australopithecus* with *Homo* but retaining *Paranthropus* is tantamount to saying that there is less difference between the former two than between either of them and the latter. This, indeed, is precisely what I do say and what I believe the facts indicate. For example, the size relationship of the canine to the post-canine dentition places *Australopithecus* and *Homo* together and separates them from *Paranthropus*; so does the morphology of dm_1, the cranial cresting pattern, the morphology of the palate, the supra-orbital height index, the pterygoid plate morphology, the nature of the mandibular ramus and one of the important muscular insertions on it, the ischial morphology and quite possibly also the foot and hand, though the evidence in the latter two cases is, as yet, meagre. Not all these features are unrelated, separate differences. Some clearly relate to different use of the masticatory complex and consequent differences in the stresses developed in the head. These thus concern a significant aspect of the biology of the animals. Supra-orbital height index reflects differences of significance with respect to brain evolution. The pelvic difference may reflect no more than different levels of adaptation to the same locomotor habit; though it is my opinion that the evidence actually indicates differences of locomotor habit.

Tobias criticizes on two grounds my unwillingness to accept the shape criterion of teeth as taxonomically valid. He seems to feel that both involve manipulation of data, at the very least, to suit my argument. First, my Table 1 "inexplicably excludes" P_4 of the type mandible of *H. habilis*. In the original description of this form the authors state that all teeth are relatively narrow, but that this is "especially evident" in the lower premolars and molars[2]. Nowhere is P_4 singled out as exhibiting this feature more strongly than other mandibular postcanine teeth. Since I was not undertaking a comprehensive study in the article concerned, I used representatives of both categories of mandibular teeth mentioned as exhibiting the

character especially well, choosing the most stable teeth in each. If narrowness is exhibited by mandibular premolars surely P_3 is as legitimate a choice as is P_4—indeed, since P_4 is known to be more variable than P_3 in hominids, the latter is much the better choice since it should show up any difference more clearly.

The second point of criticism involves my use of an incompletely developed P_3 of *Paranthropus*. Tobias emphasizes that the tooth crown had not completed its development, that I did not use it in calculating means in my 1956 monograph, but that I now include it in calculations. In both cases I took care to point out that the tooth had not yet begun to erupt and was not fully formed; thus no attempt was made to deceive the reader into thinking it was a fully formed crown since attention was deliberately directed to its incomplete condition. In the earlier instance I excluded it from calculations of means of absolute size since it was not complete. In the second instance I used it for determining shape, not absolute size. This, I pointed out, was done because the crown already almost matched the maximum length for a sample of eleven fully formed P_3 crowns from the same site, hence it was unlikely that there was still a great deal of growth to complete, and hence that it was improbable that the shape would change enough to alter the index significantly. Tobias believes that this would not be so since "much more enamel would have been added before the tooth had erupted". Enamel had already been laid down on this crown, but if the remainder of the enamel deposition had to alter the shape index to that of the other teeth, then with no further addition of enamel on the mesial and distal faces of the crown, the buccal and lingual faces would have had to receive a total of roughly 3 mm of additional enamel. It seems to me unlikely that enamel deposition would be so very disproportionate on different sides of the same premolar crown.

If this particular tooth is left out of the Swartkrans series, the observed range would be 76·0–92·8 for the eleven specimens. The broader of the two relevant teeth in the *H. habilis* type mandible has an index (using Tobias's own measurements) of 93·1, thus leaving a gap of 0·3 of a unit in the index between the two ranges. It should be remembered that the tooth here mentioned, which gave an index of 93·1 on Tobias's measurements, gave an index of 98·0 from my measurements and 115·8 from those of Leakey.

According to Tobias (Table 3) the observed range of the L/B index of P_3 of *Australopithecus* (*sensu stricto*) is 71·4–90·9 and that for *H. habilis* is 93·1–99·5; sample size being seven in the former and three in the latter case. Tobias believes that this is valid evidence that two distinct taxa are here involved. If we follow him in this belief, are we not in serious danger of arriving at the conclusion —quite logical from these premises—that the type mandible of *H. habilis* as measured by Leakey (L/B index 115·8, $N = 2$, for P_3) belongs to a different taxon from the same specimen as measured by Tobias? Clearly such a conclusion is not possible if a realistic approach is taken to variation and less reliance placed on very small gaps between ranges when these are observed ranges based on extremely small samples.

There seems to be some confusion in Tobias's remarks concerning my view that the phyletic valence of shape indices of teeth is low in hominids and cannot be used in the manner in which it has in the case of *H. habilis*. My point is that there is so much overlap in this character in the hominid group that it cannot be used as a sorting criterion. Tobias criticizes this in two respects. First, that I have used relatively small samples to demonstrate my point instead of using all the available material. Had I been attempting to demonstrate non-overlap, hence validity of the criterion, then clearly the largest possible samples should have been used since small samples are an obvious danger to the case. Since I was concerned with overlap the case is very different: I cannot see how increasing sample sizes can remove overlap which is already present on the basis of small samples. The very fact that small samples from restricted areas have been used and nevertheless proved overlap improves the effectiveness of the demonstration that the criterion is useless for sorting purposes. The *H. habilis* material is from Olduvai alone; by design I used similar local samples (which, because they are local and small, are very unlikely to be as variable as pooled samples from widely scattered sites) to show that the ranges nevertheless overlap very greatly.

Secondly, Tobias maintains that the very basis of my view is unacceptable since, "The taxonomic usefulness of a character in any specific comparison depends on its ability to differentiate between the two taxa considered. It is totally irrelevant . . . that some teeth of some other groups do not differ in L/B index. The vital fact remains that this index does show a definite difference between *H. habilis* and *A. africanus*". In other words, my comparisons between *Paranthropus*, *Australopithecus* and *Homo* are beside the point. In this view I believe that he is seriously mistaken. What two taxa are being compared by Tobias? According to him *H. habilis* and *A. africanus*; two species, that is. But these two species, according to Tobias, belong in different genera; hence when comparing them one is in fact comparing the genera in which they belong. By placing the species in two different genera one is, in effect, saying that the main difference between them are the differences between the genera *Australopithecus* and *Homo* since the only legitimate way in which the two species concerned can get into different genera is by the one possessing the sorting characteristics of *Homo* and the other possessing those of *Australopithecus*. To insist that one is here comparing only the two species and not the genera to which they belong is to misunderstand a fundamental aspect of taxonomy. In view of the position which Tobias is attempting to defend, he needs to demonstrate that the dental shape characteristics of the genus *Australopithecus* (which according to him includes the material I place in *Paranthropus*, hence this must also be included) differ significantly from those of the genus *Homo*. If he wishes to maintain that the shape index is a valid taxonomic criterion in this instance, then it is necessary that he demonstrates that by using it he can sort any specimen belonging to either of these genera into the correct genus. Clearly, if the ranges of this feature for the two genera overlap, then this requirement cannot be met.

The inability of this criterion to sort *Australopithecus* specimens from those of *Homo* is clearly demonstrated in the table given in my paper on this subject[3]. In this the most stable teeth in the groups mentioned (mandibular premolars and molars) as showing this difference most clearly are compared and it is seen that for *Australopithecus* and a large sample of *H. erectus* the means are not very different and the ranges overlap almost completely. In Tobias's tables he has added some specimens to the *Australopithecus* sample, and this, as could have been predicted, makes the overlap even greater so that scarcely any of the specimens could be sorted into the correct genus by this criterion. As was pointed out, adding modern samples of *Homo* makes the observed range for his genus considerably greater.

It might be argued that even though the tooth shape criterion is of no value at the generic level, it might be at the species level and would thus allow *H. habilis* to be distinguished from other species of *Homo*. The enormous variation in this index in modern man, all within a single species, which includes the known range for *H. erectus* as well as the ranges for the genera *Australopithecus* and *Paranthropus*, rather clearly suggests that this is not possible either.

The shape index therefore cannot be used as a sorting criterion of the known hominid genera and, on available evidence, it is improbable that it could be used at the species level either, within the genera. Consequently I

conclude that it has very low phyletic valence and that it does not serve the purpose for which Tobias is attempting to use it. He is therefore very wide of the mark in claiming that the only semblance of validity my objection has stems from the use of the one incompletely developed crown from Swartkrans. The confusion of the generic and species levels in his comparisons further invalidates his taxonomic conclusion.

My criticism of the establishment of the species *H. habilis* is that (1) variation has not been treated adequately or realistically; (2) the sorting criteria used are not valid; (3) there has been some confusion between the genus and species levels in the taxonomic analysis.

GEOGRAPHY IN CANADIAN UNIVERSITIES

By Prof. W. G. V. BALCHIN
Vice-Principal of the University College of Swansea
AND
ALICE M. COLEMAN
Department of Geography, King's College, London

THE *Commonwealth Universities Yearbook, 1965*, lists a total of fifty-five universities and colleges in Canada with the power to grant degrees. Of these, thirty-eight are exercising all their powers, thirteen are holding some or all of their powers in abeyance while in federation or affiliation with another university, one (Guelph) is a new university formed from colleges previously affiliated to other institutions, and three (Brock, Trent and Simon Fraser) are new universities with full powers but founded so recently that their first students have yet to graduate. More than a third of the universities of Canada have received their charters since 1940, mainly during the past decade.

The rate of change and of expansion in university facilities in Canada in the period since the end of the Second World War has been phenomenal. An impressive illustration is afforded by Simon Fraser University in Vancouver. It was conceived of and approved in 1963 and an architectural competition was then held for a design which would fit the 1,200-acre site selected. The Erickson-Massey plan was chosen from 71 entries late in the same year and this scheduled an opening in 1965 with 2,000 students after an expenditure of 18 million dollars on buildings. In fact the University opened on schedule in October 1965 with 2,400 students and further rapid growth is expected.

Matching this post-war explosion in university development there has been an even greater growth in the facilities for teaching and research in geography. Apart from the Universities of Toronto and Montreal, the subject was almost non-existent in Canadian universities at the outbreak of the Second World War. To-day it is well established in all the major universities and in more than half the degree-awarding institutions, a development which has largely occurred in the past decade and which doubtless owes much to the survey on the state of geography in Canadian universities undertaken in 1951 by Prof. (now Sir Dudley) Stamp for the Canadian Social Science Research Council.

An understanding and appreciation of the place of geography in the academic structure of Canadian universities involves a background knowledge of the general pattern of university evolution within the Dominion. The story begins in 1635 when the priests of Quebec City, capital of the French colony of Canada, founded the Collège des Jésuites. The Séminaire de Québec came next in 1663 and from the amalgamation of these two institutions there grew the whole system of French-Canadian university education. Laval University was the first to emerge in 1852, and secondly, in 1920, the University of Montreal, which was established as a "succursale" of Laval in 1876. Many classical colleges, each associated with one of the universities, were established during the nineteenth century and institutions giving instruction in the French language spilled over the provincial frontiers. The Collège de St. Boniface, for example, was established in Manitoba in 1818, the bi-lingual University of Ottawa in 1848 and St. Joseph's of New Brunswick in 1864.

Colleges and universities in the English-speaking tradition came later than the French foundations and it was really the American revolution which brought English-speaking education to Canada. The Empire loyalists who streamed north into Canada soon established educational institutions most of which were Anglican and appropriately named "King's College". King's College at Windsor, Nova Scotia, was founded by provincial charter in 1789 and received a royal charter in 1802. It is now located at Halifax as the University of King's College and is closely associated with Dalhousie University. In New Brunswick the Provincial Academy of Arts and Sciences became the College of New Brunswick by Provincial Charter in 1880, received a royal charter as King's College, New Brunswick, in 1828, and became the University of New Brunswick in 1859. In 1827 "King's College at York" was founded and from this emerged the University of Toronto when the name of the city was changed from York to Toronto. As part of the same trend came Queen's College at Kingston, four years after the accession of Queen Victoria. Catholic and Anglican sponsorship of universities was followed by support from other denominations, for example, Mount Alison (United Church) and Acadia (Baptist). McGill University in Montreal is an example of an institution founded by a wealthy individual without either Church or State support.

During the twentieth century the support of universities by the Provinces became predominant, for example Alberta in 1906, Saskatchewan in 1907 and British Columbia in 1908. The massive growth in facilities to match the demand for university places after the Second World War has seen the increased importance of provincial aid and also the addition of Federal Government funds. Federal sources include the National Research Council and the Social Science Research Council. The latter operates on a limited scale, but co-operates closely with the semi-independent Canada Council, which also gives financial assistance to geography on the Arts side. The Canada Council was founded in 1957 when the Federal Government allocated 50 million dollars of death duties

derived from the James Dunn estate. The capital sum has since been supplemented by other large gifts. In order to qualify for grants from certain of these sources many institutions have changed from a sectarian to a non-sectarian basis while others have amalgamated or federated into new universities.

Ontario in particular has experienced the explosion in facilities. In 1939 it had six universities—McMaster, Ottawa, Queen's, Toronto, Waterloo-Lutheran and Western Ontario. To-day it has seventeen if we include Osgoode Hall Law School, which has degree-granting powers. Even more extraordinary is the fact that most of the expansion has taken place in the past 6 years. New charters were authorized at Windsor in 1953 and Carleton in 1957, and these were followed in rapid succession by Waterloo 1959, Royal Military College 1959, Laurentian 1960, Lakehead 1962, York 1963, Trent 1963, Brock 1964, and Guelph 1964.

In western Canada the early concept of a unified provincial university is changing as a result of population pressure. British Columbia has recently chartered the new universities of Victoria (1963), Simon Fraser (1964) and the Notre Dame University of Nelson. Alberta and Saskatchewan now operate two campuses each (at Edmonton and Calgary, and at Saskatoon and Regina respectively) and these may well emerge before long as four separate universities. The rate of change is indeed so great that some of these foundations are not recorded in the *Commonwealth Universities Yearbook, 1965*.

It is against this general background of university expansion that one must set the development of geography as a discipline. Geographical courses were introduced in Toronto in 1906 and in the University of Montreal in 1910, while the universities of British Columbia, McMaster and Western Ontario followed in the 'twenties and 'thirties. A major step forward came in 1935 with the establishment of a separate Department of Geography within the University of Toronto under the direction of Prof. Griffith Taylor. It was the Second World War, however, that demonstrated to Canada, as indeed the First World War had to Britain, that geography was important and valuable both as a university discipline and as a practical subject. As a result departments of geography were founded in quick succession in many of the existing universities and were also incorporated without question in nearly all the new foundations. The sequence began with McMaster in 1942 and was followed by McGill (1945), Laval (1946), British Columbia (1946), Western Ontario (1946), Montreal (1947), Ottawa (1951), Manitoba (1954), Edmonton (1955), Carleton (1957), Waterloo-Lutheran (1959), Queen's (1960), Saskatoon (1961), Waterloo (1961), York (1962), Victoria (1962), Calgary (1963), Brock (1964), and Simon Fraser (1964). Geography is also being taught at the undergraduate level in a further ten Canadian universities, but in these full departmental status has yet to be granted. Progress has still to be made in some localities especially in the older-established universities in the Maritime provinces.

First Degrees

The vast majority of Canadian students are registered in general rather than honours degree courses. General degrees are made by passing a certain number of courses each year, that is, collecting credits. Thus the B.A. degree normally comprises five full courses each year, the B.Sc. degree six or more. Sessional examinations are held on the year's work in each course and a pass standing is required for admission to the following year. This pattern can produce very large undergraduate geography registrations in those institutions where certain geography courses are regarded as basic to some of the degree structures, or where geography courses prove popular among both arts and science students. In the United States there has been considerable criticism of the credit system of qualifying for a degree, especially when the degree is obtained by piling up credits in totally unrelated subjects, but this situation rarely obtains in Canada, where various systems of required courses make a co-ordinated pattern of undergraduate work.

The honours degree course requires concentration on either one or two subjects and sometimes means an additional year of study. The attainment of an honours level in the examinations is also a requirement for both entry to and continuance in an honours course. Many of the smaller universities and colleges have not yet progressed to the stage of offering honours degrees in geography.

Although the credit system dominates the degree structure, in many other respects it is not difficult to see the influence of the universities of England and Scotland —especially Oxford, Cambridge, Edinburgh and London —in the English-Canadian universities and departments of geography. In the French-Canadian universities, however, the traditional French pattern is strongly in evidence. The *baccalaureat* with its well-rounded classical education usually precedes specialist and university studies. This instruction is given by approximately 30 associated colleges under the supervision of universities such as Laval and Montreal. Thereafter the student enters a university where specialist training in geography is available in an '*Institut*'—which in Canada resembles the normal department of geography. Both Laval and Montreal have maintained a close contact with French universities and some professors of geography have held chairs simultaneously in Canada and France.

Higher Degrees

The situation regarding higher degrees is still in process of evolution so far as geography is concerned. Generally in English-Canadian universities a master's degree demands at least a year of study in certain prescribed courses beyond an honours bachelor's degree, and an acceptable thesis. The Ph.D. degree requires at least two additional years, prescribed courses, examinations and the presentation of a comprehensive thesis. Experience shows that studies extending over 2 and 3 years respectively are more normal. Most universities offering honours courses for the first degree also offer masters' degrees, but owing to faculty affiliation these are more often available in arts (thirteen institutions) than in science (five institutions). The Ph.D. degree in geography is awarded in nine universities. Doubtless this situation will be remedied in the course of time as the number of honours students and the volume of postgraduate work increase.

In the case of the French universities the M.A. is often a first degree and the *Diploma d'Études Supérieures en Géographie* may be more equivalent to a master's degree. There is little similarity of system between one university and another and it is valueless to try to relate the *baccalaureat, licence, diploma* or *doctorat* with supposed English equivalents. The situation is perhaps less confusing for the British with their own anomalies as between Oxford, Cambridge, Edinburgh and the civic universities, than for academics from other countries where more uniform practice prevails. There is, however, at present a great deal of discussion under the auspices of the Quebec Ministry of Education on the subject of greater standardization throughout the Province.

Staffing and Equipment

The staff-student ratio in Canadian universities is akin to that which prevails in Britain and with ratios of 1:12 common would be regarded by many as quite favourable. However, the credit and course system means that each student may be attached to several departments and that departmental staff-student ratios are much less favourable in practice. Geography departments are expanding rapidly and many have adopted the interesting

policy of trying to secure overseas nationals as their regional experts. British, American, French and European geographers are much in evidence and doubtless will remain so until the newly emergent schools of geography begin to produce Canadian geographers in quantity. At present the opportunities for highly qualified geographers are widespread in Canada, and the Dominion also suffers a 'brain-drain' south across the border to the United States.

The very large number of students taking general courses in geography at the undergraduate level has led to the establishment of a grade of graduate assistants in most departments in order to help with practical classes, laboratories and field work. Graduate assistants normally study for higher degrees at the same time. Good honours degree students from Britain are especially sought for these posts and there should be a steady and continued demand for such for many years to come. The posts are financed in a variety of ways. Most universities award their own graduate fellowships and assistantships with stipends of 2,000 dollars and more. Commonwealth fellowships may be held in Canada and Provincial fellowships are available, notably in Ontario and Alberta, while the National Research Councils and the Canada Council also award scholarships and fellowships. Application for many of these awards may be made by United Kingdom subjects.

For the young geographer anxious to acquire overseas experience, research training and a higher degree, Canada offers a wide range of possibilities. Intending migrants should, however, match their research interests with appropriate localities and/or departmental interests. While most departments are broad-based, some have developed specialist interests or can offer specialist facilities. Each year most departments issue brief descriptive pamphlets which can be obtained on request.

The physical facilities available to geography in Canadian universities are rapidly catching up with, and in some cases moving ahead of, those available in the United Kingdom. Completely new buildings for geography have recently been occupied or are under construction in most universities where the subject is represented—notably Alberta (Edmonton and Calgary), Carleton, Manitoba, McGill, McMaster, Simon Fraser, Toronto, Victoria, Waterloo and Western Ontario. Canadian geographers, like their British colleagues, have given a good deal of thought and attention to departmental buildings over the past 5 years and they recently requested Prof. Hans Carol of York University, Toronto, to act as a central clearing-house for planning details. It is interesting to note that, whereas in the 1951 report on geography in Canadian universities Prof. Stamp included a plea for map laboratory space as an essential requirement, this is now taken for granted and many departments have included specialist laboratories for physical geography, climatology, cartography, photogrammetry and pedology. Technical, secretarial and draughting support does not yet match that available in the United Kingdom, but this can be more easily remedied.

Field Work

Unlike laboratory provision, field work in Canadian universities tends to lag behind that in Britain. There are in fact a number of inhibiting factors such as the length and rigour of the winter which admittedly makes field work difficult during much of the academic session, and this is aggravated by the early termination of the session in May. Field work is also not easy to fit into course and credit systems, and students who are working their way through college find it difficult to attend long-vacation field courses. Only honours and postgraduate students can be conveniently managed in the field when general groups run into the hundreds, while the immense and uniform extent of many physical and cultural landscapes makes comparative studies difficult and encourages the widespread use of air photographs as substitutes.

Canadian geographers, however, are grappling with this problem and in many cases with notable success. Courses on field work and field techniques are being introduced into the schemes of study either on a voluntary basis (for example, Carleton) or half credit basis (for example, Western Ontario), while in other departments (for example, Toronto, McMaster, Waterloo and Alberta) excursions are organized to areas of geographical interest in Canada or the United States. The province of Quebec has a long-standing field tradition with weekly excursions at Montreal and ten excursions during the session at Laval. The McGill Department of Geography has established field stations at Schefferville, Northern Quebec; at Barbados in the West Indies; at Rupununi in British Guiana; and at Axel Heiburg Island in the North West Territories. In this respect Canadian geographers have leapt ahead of their colleagues in Britain. Mention should also be made of the pioneer field studies being undertaken by the Geographical Branch of the Department of Mines and Technical Surveys. The field activities of this Government Department include expeditions involving substantial transport resources such as helicopters and light aircraft; organized as a regular and normal part of the work of the Geographical Branch, these Government activities are without parallel in Britain.

Summer Schools

Another feature of considerable importance is the summer school. Although summer schools are not held annually by all departments there are several normally available each year usually lasting from 6 to 8 weeks in July and August. The summer school has many functions in Canada. In some cases it grants credits towards a degree, in others it is a valuable refresher course for teachers. The summer school can also function as an alternative to sessional field work, which, as we have seen, can be difficult in the Canadian winter. The summer schools attract not only Canadians but also Americans, while some schools, notably McGill at Stansted and British Columbia at Vancouver, have become internationally known. It is customary at most summer schools to invite leading British, American and European geographers to contribute specialist courses in support of those given by the resident staff. Details of the summer schools are published by the organizing departments and are available on request.

Research

The full and continuing development of a subject depends ultimately on active research and publication. The steadily improving facilities and increasing number of geographers at work in Canadian universities in the past decade have greatly increased the volume of research work. In addition the Geographical Branch of the Department of Mines and Technical Surveys undertakes a great deal of research work; it is one of the six branches of the Department which is a complex federal research organization specializing in the earth sciences and related fields. The Provincial Government of Quebec also maintains a geographical research establishment known as the Centre d'Études Nordiques at Laval University.

Canadian geographers are now well served for the publication of their research. Pioneer work in this field was undertaken by the Société de Géographie de Québec, which published a Bulletin from 1880 until 1937 and, jointly with the Société de Géographie de Montréal, from 1942 until 1944. This gave place to the *Revue Canadienne de Géographie* which is the organ of both the Société de Géographie de Montréal and of the Institut de Géographie de l'Université de Montréal. The oldest uninterrupted series is the monthly *Canadian Geographical Journal* which has been published by the Royal Canadian Geographical

Society since 1930. In 1951 the newly-formed Association of Canadian Geographers began issuing the *Canadian Geographer* as a quarterly. It also produces a valuable annual report which lists geographical research publications and statistics relating to geography in Canadian universities. This association now has a membership of more than six hundred of whom half are associate or student members. Its British Columbia Division has been publishing *Occasional Papers* since 1960.

The Geographical Branch issues a range of publications including an annual *Bibliographical Series* and an irregular series of *Geographical Papers*, both since 1950, the *Geographical Bulletin* since 1951 and memoirs since 1953, as well as the Canadian atlases and gazetteers and various coloured maps. The *Geographical Bulletin* became a quarterly in 1965. The *Cahiers de Géographie de Québec* have been published by the Institut de Géographie de l'Université Laval since 1952 and the Centre d'Études Nordiques has produced a series of *Travaux Divers* appearing irregularly since 1963. Mention must also be made of *The Cartographer* which made its début as a twice-yearly publication during 1964. Although it is published by the Ontario Institute of Chartered Cartographers, it is strongly slanted to the cartographic interests of the geographer. Papers in Canadian periodicals are not necessarily in the same language as the title of the journal. English articles are often supported by a French summary and vice versa.

There are almost limitless possibilities for geography in Canada. Covering an area of 3·75 million square miles, its population is still only 20 million. Much of the territory has yet to be investigated and there are numerous problems in the fields of both physical and human geography awaiting attention. Hand in hand with the opening up of the country there is a growing demand for experts in geographical education, land use assessment, town and country planning, climatology, cartography, pedology, marketing and intelligence work—avenues of activity and careers into which the appropriately trained geographer fits with ease.

OBITUARIES

Prof. N. I. Grashchenkov

On October 8, 1965, one of the most outstanding Soviet neurologists and neurophysiologists, Prof. Nikolai Grashchenkov, died at the age of sixty-five at the height of his creative activity.

From the first, Prof. Grashchenkov strove in all his scientific activity to establish the physiological method in neurology. He understood clearly that the extremely subtle experiments which Nature performs by effecting the central and peripheral formations of the nervous system in man considerably enlarge the perspectives of creating real human physiology. Throughout his scientific activity, N. I. Grashchenkov carried these principles into practice. As part of his training, Grashchenkov spent 2 years at the most advanced physiological laboratories of the world at the Universities of Cambridge, New Haven, New York and Boston. When he returned to the Soviet Union, he placed experimental investigations at his offices on a broad footing.

During the Second World War, Prof. Grashchenkov turned his investigations in clinical neurophysiology towards the war effort, and at the same time he became consulting physician at one of the Field Forces. It was there that he formulated the hypothesis of the malfunction of the synaptic structures in the central nervous system being responsible for reversible disorders. He founded the doctrine of functional asynapsy in some pathological conditions of the brain and spinal cord, which still has great theoretical and practical importance.

In his investigations of synaptic processes in the central nervous system, Grashchenkov concentrated his attention on the role of bio- and physico-chemical interrelations in some forms of nervous pathology.

Together with his collaborators he published a large number of books, articles and monographs dealing with the role of the hypothalamus in the neuro-humoral-hormonal regulation of brain functions. These investigations were of great importance in the elucidation of the problem of homoeostasis in physiology and in clinical neurology. He showed that laboratory, clinical or physiological examinations alone did not give a reliable indication of the status and functions of healthy or sick organisms and of the work of different organs or physiological systems. These problems could be solved only by means of consistent dynamic study of physiological and biochemical parameters.

One of the features of the investigations carried out at Prof. Grashchenkov's laboratory was the application of dosed-out functional load, making it possible to find homoeostatic limits and in each case to expose the links most open to injury in the system of homoeostatic forces of the organism. This approach made it possible to put into practice a number of new therapeutic methods in the treatment of some forms of hypothalamic pathology.

Grashchenkov paid much attention to the physiological analysis of traumatic injuries of the brain and to the problem of muscular diseases, particularly myasthenia. The most important problems of neurophysiology, such as the questions of function localization in the brain, of sleep and arousal, behaviour and the orientating reaction, lay within the range of his interests. Grashchenkov's works on virus encephalitis are also well known, and his early results on this subject still retain their value and scientific significance.

Grashchenkov combined his scientific and pedagogical work with great organizational activity in the field of public health in the U.S.S.R. He held a number of responsible posts in the Ministry of Public Health, and for a number of years he was the president of the Byelorussian Academy of Sciences. In recent years, also, he was one of the leaders of the Physiological Department of the U.S.S.R. Academy of Sciences.

Grashchenkov's life shows the possibilities open to people of talent in Soviet society. The son of a peasant, a village cowherd, he took part in the Civil War and became one of the leading scientists not only in home but in world medicine. He was, for some years, assistant director-general of the World Health Organization; he repeatedly represented the U.S.S.R. in different international organizations, and participated in many international scientific symposia. In the person of Nikolai Grashchenkov, Soviet medicine has lost one of its most gifted and versatile representatives. G. Kassil

Dr. I. L. Chaikoff

Dr. Israel Lyon Chaikoff died on January 25, 1966, in Berkeley, California. He was born in London on July 2, 1902, and he grew up in Toronto. He graduated from the University of Toronto in 1924 and immediately embarked on his career of research in physiology, which started in association with the late Prof. J. J. R. Macleod, in the department where insulin had recently been discovered by Banting and Best. The impact of the discovery had many effects; one of these was to shape

the lives of contemporary young research workers in the medical sciences. One of the most distinguished of these was I. L. Chaikoff. He received the degrees of Ph.D. in 1927 and M.D. in 1930 from the University of Toronto, after which he joined the faculty of the University of California at Berkeley. Here he became a full professor in 1942. His laboratory maintained an unbroken flow of eminent contributions to biochemical endocrinology and metabolism. Many of his students continued their work in these fields as prominent members of the faculties of other universities.

Chaikoff was an originator in metabolic research, with the broadest of interests in biochemistry, medicine and nutrition. He was one of the first to introduce radioisotopes in biology and medicine, and he pioneered with iodine-131, phosphorus-32 and carbon-14 in research on the thyroid, the pancreas, and the liver. For years he investigated the biochemical changes following experimental pancreatectomy, especially with regard to the aetiology of fatty infiltration of the liver. He made numerous investigations in arteriosclerosis, phospholipid metabolism, cholesterol biosynthesis (including the role of squalene as a precursor), lipogenesis, the role of insulin in intermediary metabolism, fatty acid oxidation, carbohydrate metabolism, the action of oestrogens, anterior pituitary hormones, adrenal steroids, and other fields involved with the function of the body.

He shunned publicity and public appearances, preferring to devote himself to his laboratory, to the teaching and training of students, and to the encouragement of his large staff of scientific associates and collaborators, among whom he inspired many loyal friendships. He objected strongly to any form of pretentiousness and he had wide literary interests. He was a man of the highest standards in research and scientific writing and he was keenly conscious of the history and progress of the biological sciences. He was a prolific contributor to the leading scientific journals in his field, with a list of more than 400 publications in them. He held a Guggenheim fellowship in 1941–42, and a Miller research professorship during 1963–65. He was a Harvey lecturer in 1952, he received the Medal of the Endocrine Society of the United States in 1958, and he was faculty research lecturer at the University of California in 1958. He was married in 1949 to Isabelle Rawls, who survives him.

T. H. Jukes

NEWS and VIEWS

The Royal Society of Edinburgh

Sir Lawrence Bragg has accepted the invitation of the Royal Society of Edinburgh to deliver the James Scott Lecture, 1966, at the Society's ordinary meeting on March 6, 1967. The Keith Prize for the period 1963–65 has been awarded to Dr. Reinhold Fürth, formerly reader in theoretical physics, Birkbeck College, University of London, for his paper on the statistical thermodynamics of liquids published in the *Proceedings* of the Society during the period of the award and in recognition of his many valuable contributions in the same field.

Geology in the University of Cambridge : Prof. O. M. B. Bulman, F.R.S.

Prof. O. M. B. Bulman resigns from the Woodwardian chair of geology in the University of Cambridge in October; the chair is the oldest geological endowment in Great Britain. Having been successively University demonstrator in geology (1931–34), lecturer in palaeozoology (1934–44), and reader in palaeozoology (1944–53), he was elected to the chair in 1955. He had entered the University of Cambridge as an 1851 Exhibition Senior Student at Sidney Sussex College in 1926 following Ph.D. studies at the Imperial College of Science and Technology under Prof. W. W. Watts, and he returned to Cambridge in 1931 after holding teaching appointments in zoology and geology at Imperial College. Throughout his researches, Prof. Bulman has been predominantly a student of the Graptolithina, a group of fossils extensively used in classifying the Ordovician and Silurian strata. He has applied ingenious techniques and gifted powers of illustration to the better understanding of the morphology and evolutionary paths of these fossils. He and his research students have given remarkable impetus to studies of the group and of its occurrences in various parts of the world. Prof. Bulman has devoted much time to benefit the activities of scientific organizations and has held the office of president of Section C (Geology) of the British Association for the Advancement of Science (1959), the Palaeontological Association (1960–62) and the Geological Society (1962–64). In addition, for more than thirty years he has been a co-editor of the *Geological Magazine*. He is at present a member of the Natural Environment Research Council's Geology and Geophysics Committee and a Trustee of the British Museum (Natural History). At Cambridge he has developed a more diversified and adequately accommodated research school and has recently taken a prominent part in the reorganization of the Natural Sciences Tripos and postgraduate studies there.

Prof. H. B. Whittington

Prof. H. B. Whittington, who will succeed Prof. O. M. B. Bulman in October as Woodwardian professor of geology in the University of Cambridge, will take up that appointment with a record of world experience more varied than that of any previous occupant. A graduate, Ph.D. and D.Sc. of Birmingham, he went to Yale as a Commonwealth Fellow in 1938 and in 1940 moved to Rangoon to teach at Judson College. During the Second World War, he became attached to an ambulance unit in Burma, whence he proceeded to Ginling College, in Chengtu. In 1945 he returned to Birmingham, but the invitation which he accepted in 1949 to go to Harvard University as a visiting lecturer was rapidly turned into the offer of a more permanent appointment and for years he has been professor of geology at Harvard and curator of invertebrate palaeontology in the Museum of Comparative Zoology. His copious list of publications includes a worthy number relating to the stratigraphy of the British Isles and America and even one or two on the physiology of Szechuan, but it is as a palaeontologist, and especially as an expert on the trilobites, that he has achieved an international reputation. In 1955 he became secretary of the Palaeontological Society of America and he has just completed his term as president of that body. The Geological Society of London awarded him the Bigsby Medal in 1957. It is a testimony to his international reputation that he has been asked by the Geological Survey of Canada to direct excavations in the Middle Cambrian Burgess Shales of British Columbia which revealed to Walcott so much that was previously unknown and unsuspected in the animal world. Continuation of this direction after next summer will presumably be from Cambridge.

Applied Mathematics in the University of Manchester: Prof. L. Mestel

Dr. Leon Mestel, University lecturer and Fellow of St. John's College, Cambridge, has been appointed to a new chair of applied mathematics in the University of Manchester. Early in his research career, Dr. Mestel attracted notice by new ideas which he put forward on the energy source of white dwarf stars. Difficulties had arisen if the source were attributed to nuclear processes; Dr. Mestel showed that the difficulties were overcome if the energy came from a cooling process. Subsequent research has amply confirmed this theory. In 1954, he was awarded a Harkness Commonwealth scholarship. While at Princeton University he worked with Prof. Lyman Spitzer on problems of star formation. In their joint work, important new ideas on the significance of an interstellar magnetic field and of interstellar grains were put forward. These ideas have been incorporated in all subsequent discussions of the star formation problem. Returning to Cambridge, Dr. Mestel was appointed University lecturer in mathematics. In 1957 he was elected a Fellow of St. John's College. His interests in cosmic electromagnetism have continued, and in recent years he has been much concerned with applying this subject to problems of cosmogony and of stellar magnetism.

Mechanical Engineering in the University of Sussex: Prof. F. J. Bayley

Dr. F. J. Bayley has been appointed the first professor of mechanical engineering in the University of Sussex. Dr. Bayley has been reader in gas dynamics at the University of Newcastle since 1959, in the Department of Mechanical Engineering where he had previously been a lecturer since 1955. After graduating at Newcastle in 1948, he specialized in fluid mechanics, thermodynamics and heat transfer. For his original contributions to these subjects he was awarded successively the degrees of M.Sc. (Dunelm) in 1951, Ph.D. (Dunelm) in 1955, and D.Sc. (Newcastle) in 1964. After taking his first degree he was appointed scientific officer at the National Gas Turbine Establishment at Pyestock, where he remained for 3 years until he was appointed a research engineer at the Pametrada Research Station in 1951. Two years later he returned to the then King's College, Newcastle, where he held a Clayton research fellowship from the Institution of Mechanical Engineers until he was appointed a University lecturer. Dr. Bayley has become well known in recent years as a consultant on special regenerator and heat-exchange problems and has advised a number of firms and institutions in regard to the design of such equipment, both in Britain and in the United States.

William Whewell, F.R.S.—a Versatile Scientist

Among a number of scientists who have been eminent in more than one field, William Whewell, who died 100 years ago on March 6, was particularly remarkable. This Master of Trinity had so many activities as tutor and lecturer at Cambridge and as professor of mineralogy, as well as a science writer and author of full-scale texts, that it is surprising to look back on all his other work. The son of a master carpenter, Whewell went to Cambridge in 1812 and took various prizes, including the Chancellor's Medal for English, while all the time he was apparently a mathematician. He became second wrangler, wrote texts on mechanics, and always strove to improve mathematics teaching at Cambridge. Yet, after travels abroad, Whewell was equally noteworthy for dissertations on architecture, while in mineralogy and crystallography his papers in the *Philosophical Transactions of the Royal Society* as well as of the Cambridge 'Phil'—of which he was a founder member—were such that it seemed no surprise to find him elected to the chair of mineralogy in 1828. Whewell was a 'universalist', as his contemporaries put it. He naturally had critics, since he had a finger in many a pie, so much so that Sydney Smith commented: "Science is his forte, omniscience his foible". Yet though a theorist and philosopher rather than an experimentalist, Whewell benefited many of the branches of science in which he was interested. In geology, Whewell helped Lyell in nomenclature, while in electrical science students to-day scarcely realize that it was Whewell who introduced such everyday terms as 'ion' in his association with Faraday. Whewell was an acclaimed expert on the theory of tides, with fourteen memoirs in the *Transactions* of the Royal Society. President of the Geological Society and of the British Association for the Advancement of Science, and author of a classical three-volume *History of Inductive Sciences*, Whewell could write as well on astronomy as he could (after ordination) on theology. To appreciate the full breadth of his interests one must turn to the *Dictionary of National Biography*, in which whole columns are devoted to his publications alone.

British Government Aid Overseas

In reply to questions in the House of Commons on February 8, the Parliamentary Secretary to the Ministry of Overseas Development, Mr. A. E. Oram, said that British Government disbursements of economic aid were provisionally £189 million in 1965, compared with £160 million in 1963 and £191·6 million in 1964, the latter figures being 0·59 and 0·66 per cent of the gross national product, respectively. About £147 million of the 1965 total went to the Commonwealth. The Government's target for gross official aid in 1966–67 was £225 million. In a written answer, the Minister, Mr. A. Greenwood, stated that financial assistance was not being given to any African country which supported the illegal régime in Rhodesia. Britain's total bilateral economic aid to independent African countries in 1964–65 was £69·6 million, of which £17·1 million was for technical assistance; of this £63·7 million and £16·8 million, respectively, was to Commonwealth countries. In a written answer on February 10, Mr. Greenwood gave bilateral advances (including Exchequer advances to, but not total overseas investment by the Commonwealth Development Corporation) as £139·2 million in 1963, £173·2 million in 1964 and £172·3 million in 1965. Of these totals, £119·6 million, £153·7 million and £151·7 million, respectively, were for Commonwealth countries, and £22·5 million, £23·6 million and £28·6 million, respectively, for technical assistance to Commonwealth countries.

Articulated Ship

In reply to a question in the House of Commons on February 8, the Joint Parliamentary Secretary to the Ministry of Technology, Mr. R. Marsh, said that an articulated ship had been devised by a firm of naval architects. The National Research Development Corporation had already announced its willingness to consider sharing the cost of development of this ship as a joint venture if a suitable industrial partner could be found. The Corporation had for some years been supporting the development of *Dracones*, flexible containers that could be towed on water and used for the bulk transport of liquids. *Dracones* were already in production and operating successfully in several parts of the world.

Computer Programme Library

In reply to another question on February 8, Mr. Marsh said that the Computer Programme Library of the European Nuclear Energy Agency collected and distributed magnetic tapes on which were recorded data related to fundamental scientific and engineering problems in the nuclear field. The Library did not handle material relating to the evaluation of nuclear installations or

costings. Since it became operational in May 1964, the Library had received 299 computer programmes, of which 32 were from the United Kingdom. The Library was now nearing the end of its first three-year term and proposals relating to the Centre were being considered by the Government which would then decide on its policy towards the Centre.

Patent Office

In a written answer in the House of Commons on February 10, the Minister of State, Board of Trade, Mr. G. Darling, stated that six organizations had made representations to the President against moving the Patent Office from London. The President intended to arrange to move the Patent Office to a suitable site in Croydon, but the Library would remain in Central London and the Printing and Sales Branch at St. Mary Cray.

Committee on the Civil Service

In a statement in the House of Commons on February 8, the Prime Minister said that the Government accepted the recommendation of the Estimates Committee that a committee should be appointed to examine the structure, recruitment and management, including training, of the Home Civil Service. Lord Fulton had agreed to be chairman of this committee. The other members would be Sir Philip Allen, Sir Edward Boyle, Sir William Cook, Sir James Dunnett, Sir Norman Kipping, Prof. Lord Simey, Mr. W. C. Anderson, Mr. N. Hunt, Mr. R. Nield, Mr. J. Wall and Mr. S. Williams. The very broad terms of reference would require a fundamental and wide-ranging enquiry in the tradition of the great enquiries of the past, such as Northcote–Trevelyan in 1853 and the Tomlin Commission in 1931, and he hoped that its recommendations would enable the Civil Service to meet Britain's needs for many years to come. Mr. Wilson emphasized that the decision to set up this committee did not mean that the Civil Service had in any way been found lacking by the Government in its present operations. On the contrary, it was the experience of Ministers that the Service met the demands put on it with flexibility and enterprise. Nor did the willingness to consider changes in the Civil Service imply any intention of the Government to alter the basic relation between Ministers and civil servants. Civil servants remained the confidential advisers of Ministers, who alone were answerable to Parliament for policy: no change was envisaged in this fundamental feature of the parliamentary system. In reply to Mr. Heath, who welcomed the statement, Mr. Wilson said that it would be within the terms of reference and competence of the committee to enquire into all aspects of the functioning of and recruitment to the Civil Service. An important working party was already considering training, and the result of that enquiry would be made available to the new committee. While welcoming the report of the Estimates Committee on recruitment to the Civil Service as an extremely valuable contribution to the investigation of this subject, Mr. Wilson added that he did not necessarily accept all the conclusions of its report. He also added that it would be right for the committee to enquire into the question of exchanges between the Civil Service and the universities, business and local government. As regards wider recruitment, in the past 18 months there had been considerable success in attracting from universities and industry highly suitable persons to help with planning and with scientific and technological work, and there had been the greatest possible effort to widen the field of recruitment. The committee would also consider the possibilities of secondment and part-time service. A similar statement was made in the House of Lords, also on February 8, by the Earl of Longford, who, in reply to Viscount Dilhorne's question, assured him that the Legal Civil Service fell within the terms of reference of the committee.

British Government Aid Overseas

In the article appearing under the above heading on p. 1153 of the December 18, 1965, issue of *Nature*, the figures given as "British Government contributions in 1964–65" are, in fact, the contributions over the period 1946–47 to 1964–65. The figures for the year 1964–65 are, in fact, £9 million to the International Development Association, £3·6 million to the United Nations Expanded Programme of Technical Assistance and Special Fund, £1·9 million to the United Nations Relief and Works Agency, £0·3 million to the United Nations Children's Fund, £0·2 million to the United Nations Assistance to the Congo, £0·6 million to the World Food Programme and £3·2 million to the Indus Basin Development Scheme.

Medical Education in the United States

A conference to consider curriculum, programming and planning in medical schools and teaching hospitals was held by the New York Academy of Sciences during March 1965, and supported in part by grants from the Alfred P. Sloan Foundation, the Commonwealth Fund, the Russell Sage Foundation and the New York Chapter of the American Institute of Architects. A record of the conference has been published and includes papers on medical schools and teaching hospitals; curriculum, programming and planning; the mainstream of American medical education, 1765–1965; development of a new medical school; past experiences and considerations for the future; research in medical education participation of faculty and students; experimentation in medical education; the student, the patient and the university; biophysics and medical engineering; the relationship between medical education and medical practitioners; teaching and research; behavioural science in the medical curriculum; the science of nutrition in the medical curriculum; the humanities in the medical curriculum; budgeting the operation of the medical school; introduction to physical programming and planning; criteria for planning; long-range planning of the medical centre; and architectural programming and planning for the medical centre (*Ann. N.Y. Acad. Sci.*, 128, Article 2: *Medical Schools and Teaching Hospitals: Curriculum, Programming and Planning*. By Walter H. Blucher and 33 other authors. Pp. 457–720. New York: New York Academy of Sciences, 1965. 5 dollars).

Supply of Anti-serum in India

An indication of the problems in public health which confront an over-populated sub-continent such as India is shown in the annual report of the King Institute of Preventive Medicine, Guindy, for 1962–63 (By Dr. S. Govindarajan. Pp. 8+2. Guindy, Madras: King Institute of Preventive Medicine, 1965). The stock of anti-serum at the Institute was not satisfactory during the year under review, since no foreign exchange was released during the previous two years towards the purchase of foreign sera. Sera from indigenous sources were several times costlier and were not available in adequate quantities whenever they were required. The manufacture of anti-serum at the King Institute covers only a small part of the requirements, and thus purchases have to be made from abroad or from indigenous sources to supplement local manufacture. There are few institutions and firms in India which actually manufacture anti-sera. The majority of the firms which supply anti-sera are merely representatives of foreign firms, arranging the supply from other countries through the State Trading Corporation. The price of sera fluctuated widely and the sera were not available in adequate quantities. The time of supply was uncertain and could not be relied on. Such a situation created a heavy burden on the Department of Anti-toxins at the Institute.

Radiochemistry of Chromium and Rhodium

THE Sub-committee on Radiochemistry, one of several sub-committees working under the Committee of Nuclear Science within the National Academy of Sciences–National Research Council, is responsible for the publication of a series of monographs, each of which collects into one volume pertinent information required for radiochemical work with an individual element. These monographs are revised from time to time to bring the information up to date. Monograph *NAS-NS*-3007, issued in December 1964 and compiled by J. Pijck (University of Ghent), deals with chromium, and *NAS-NS*-3008, issued in May 1965 and compiled by J. C. Armstrong (Florida State University) and G. R. Choppin (Hazelton Nuclear Science Corporation, Palo Alto, California), with rhodium (*NAS-NS*-3007. *Radiochemistry of Chromium*. By J. Pijck. Pp. v+64. 75 cents. *NAS-NS*-3008: *Radiochemistry of Rhodium*. By James C. Armstrong, jun., and Gregory R. Choppin. Pp. vi+75. 1 dollar. Washington, D.C.: National Academy of Sciences–National Research Council. Available from the Clearing-house for Federal Scientific and Technical Information, National Bureau of Standards, U.S. Department of Commerce, Springfield, Virginia, 1965). Both monographs are revised and expanded versions of earlier editions. They include reviews of the nuclear and chemical properties of the elements, discussions of methods of sample dissolution and of separation reactions, descriptions of counting techniques and a compilation of radiochemical separation procedures.

Building Economics and Cost Planning

CERTAIN trends in the building industry, not only in Britain, but also in many other countries, are discernible in modern developments designed to break away from strictly traditional procedures, to establish firmly a more rational code of building economics and a new concept of what has come to be known as 'cost planning'. Contemporary studies of building conditions to-day have conclusively shown that purely technical problems of construction in developed countries are relatively insignificant when compared with problems of cost and labour estimating, budgetary control at all levels, and an urgent need to improve communications throughout the industry. This theme is the subject of a stimulating paper by T. W. Miners entitled "Some Aspects of Building Economics and Cost Planning" (National Building Research Institute, South African Council for Scientific and Industrial Research. CSIR ref. R/Bou 122. Reprinted from *South African Architectural Record*, 50, No. 2; February 1965). "Cost planning, in its widest sense, may be seen as an attempt to rationalize the cost aspects of a building project, from conception of the idea to build, through the design and construction phases and then finally throughout the life of the building until the period of economic obsolescence has been reached."

Mr. Miners discusses the different types of economic investigations undertaken in co-ordinating national interests, what he calls 'fringe' interests, and those of builders, group interests (such as local authorities), manufacturers, investors, and, last but not least, the interests of the client: ". . . he is the most important person to the industry". In the paragraphs on "Cost Planning and the Design Process", the technique of 'cost planning' implies the method used during the design process of keeping the cost of a building project within a predetermined sum; it includes preparation of the 'cost plan', and also the following stages of 'cost checking'. Fundamentally, this scheme of 'cost planning' is envisaged as a bridge between national, design, construction and investment interests; these are closely interrelated and dependent on each other. Some re-organization of the industry along these lines would appear to be inevitable and this essay makes a strong case for its serious consideration. Fully aware of the potential advantages of 'cost planning', the National Building Research Institute has already embarked on a programme of research in this field, including building economics in the wider sense, in collaboration with the Industrial Economics Division of the Council for Scientific and Industrial Research.

Arctic Stratigraphy

The Triassic Stratigraphy of Svalbard is an example of the major advances being made in many parts of the Arctic from the previous reconnaissance level of geological knowledge (Norsk Polarinstitutt. Skrifter Nr. 135. By S. H. Buchan, A. Challiner, W. B. Harland and J. R. Parker. Pp. 92. Oslo: Norsk Polarinstitutt, 1965. 15 kr.). It is the result of work carried out by the group directed in the University of Cambridge by W. B. Harland. It contains a review of many scattered earlier publications, but consists mainly of new and detailed observation, much of it clearly presented in diagrammatic measured sections and summarized in a fence diagram. A new scheme of stratigraphical subdivisions is proposed in line with modern international usage. A lengthy "Index to Svalbard Triassic Fossils" includes all published fossil determinations and provisional determinations of the new Cambridge material. Probably the most interesting section for the non-specialist reader is one comparing these Triassic rocks with those of other Arctic areas. This demonstrates the key role of Svalbard in working out the complex pattern of movements between the various Arctic–Atlantic landmasses.

Life Insurance Medical Research Fund of Australia and New Zealand

APPLICATIONS are invited by the Life Insurance Medical Research Fund of Australia and New Zealand for financial assistance to conduct research broadly related to cardiovascular function and disease. The Fund will award grants-in-aid to non-profit institutions in Australia or New Zealand, equipped with the basic facilities for research, to support a specific programme of fundamental or clinical research under the direction of an experienced full-time investigator. Such grants will be made initially for one to three years. The Fund is also offering research fellowships to university graduates to engage full-time in fundamental or clinical research. Such fellowships will be of two types: (*a*) fellowships to work in Australia and New Zealand will be granted initially for one year to medical graduates, who need not have previous research experience; (*b*) travelling fellowships will be granted for a period of two years abroad and a third year in Australia or New Zealand to graduates with at least two years' experience in research. Travelling expenses will be provided for the fellow and his family. Further information and forms of application can be obtained from Dr. H. M. Whyte, medical director, Life Insurance Medical Research Fund of Australia and New Zealand, Box 4134, G.P.O., Sydney, New South Wales. The latest date for receipt of applications is July 1, 1966.

Travelling Research Fellowships to Denmark and Sweden, 1966–67

APPLICATIONS are invited for the Carlsberg–Wellcome and Wellcome–Swedish travelling research fellowships, 1966–67. The object of these is to encourage working visits, on an exchange basis, between Danish and British, and Swedish and British, investigators in any branches of the natural sciences which have a bearing on human and animal medicine. One of each fellowship is awarded annually to a graduate from the United Kingdom for a year's work in the exchange country, and one Swedish and one Danish candidate annually may work in the United Kingdom. The stipend may range from £1,000 to £2,000 per annum; travelling and some incidental

expenses are provided in addition. The Carlsberg–Wellcome fellowships are arranged with the Carlsberg Foundation in Copenhagen; the Wellcome–Swedish fellowships are provided jointly by the Medical Research Council of Sweden and the Wellcome Trust. Candidates in the United Kingdom can obtain further information from the Secretary, the Wellcome Trust, 52 Queen Anne Street, London, W.1. Completed applications must be submitted by April 9, 1966.

Guinness Awards for Science and Mathematics Teachers

The Guinness Awards for Science and Mathematics Teachers are now being extended to Africa. They are being carried out in association with the Department of Education in Tropical Areas of the University of London Institute of Education, Malet Street, London, W.C.1, together with the assistance of a number of Departments and Institutes of Education in Africa, Ministries of Education and the British Council.

Nature Subscriptions

It is regretted that the charges for direct postal subscriptions to *Nature* printed on the back page of the index for Volume 207 are incorrect. The present charges are:

	Inland	Overseas
12 months	£14 0 0	£13 15 0
6 months (26 issues)	£7 0 0	£6 17 6
3 months (13 issues)	£3 10 0	£3 8 9

Payment from abroad should be made by International Money Order or by cheque payable to Macmillan (Journals), Ltd. (Macmillan (Journals), Ltd., is now at 4 Little Essex Street, London, W.C.2.)

Organization of the Scientific Civil Service

It has been brought to the Editor's notice that the fourth paragraph of the review of the Report of the Tennant Committee, published on p. 113 of the December 18, 1965, issue of *Nature*, is open to misinterpretation. The figures given in the first sentence of the paragraph relate to the unestablished staff referred to in the preceding paragraph. Thus, in the scientific and experimental officer classes taken together, 80 per cent of the officers serving in a temporary or unestablished capacity have been employed in the Civil Service for 5 years or less, and in the scientific officer class 60 per cent and in the experimental officer class 50 per cent of the unestablished staff have been employed for 2·5 years or less.

University News:

Edinburgh

Dr. R. M. Cormack has been appointed senior lecturer in statistics. The following lecturers have also been appointed: Dr. C. P. Mayers (pathology); Mr. D. A. Williams, Mr. C. W. D. Peare and Mr. E. F. Harding (statistics).

London

A chair and Research Group in Traffic Studies have recently been established at University College, London, and Prof. R. J. Smeed, formerly deputy director (traffic and safety) of the Road Research Laboratory, and more recently chief scientist at the Ministry of Land and Natural Resources, has been appointed holder of the chair and director of the Group.

Manchester

Prof. D. H. Valentine, professor of botany in the University of Durham, has been appointed George Harrison professor of botany and director of the Experimental Grounds in succession to Prof. C. W. Wardlaw, who is retiring on September 30. The following appointments have also been made: *Readers*, Dr. A. Allsopp (cryptogamic botany); Dr. K. J. Dormer and Dr. E. W. Simon (botany); Dr. W. C. E. Higginson, Mr. O. S. Mills, Mr. N. L. Paddock and Dr. G. F. Smith (chemistry); Dr. F. P. Stainthorp (chemical engineering); *Senior Lecturers*, Dr. F. R. Jevons (biological chemistry); Dr. L. Barden (soil mechanics); Dr. R. A. J. Shelton (metallurgy); Dr. G. A. Lumb (medical chemistry); Dr. G. Taylor (immunology); Dr. G. C. Wood (chemical engineering); Dr. W. D. Humpage, Dr. D. C. Northrop, Dr. L. M. Wedepohl, Dr. T. E. Broadbent and Dr. D. Tipping (electrical engineering); Mr. S. V. Fagg (mathematics); Mr. N. D. Whitehouse (mechanical engineering); Dr. I. G. Edmunds (physics); *Lecturers*, Dr. S. Dunstan, Dr. M. G. Barlow and Mr. M. J. Ware (chemistry); Dr. G. S. Taylor (botany); Dr. J. A. Joule (organic chemistry); Mr. D. G. Buchanan, Mr. B. E. Jones and Mr. P. Swarbrick (electrical engineering); Dr. J. M. Anketell and Mr. J. Esson (geology); Mr. R. D. Gregory, Mr. J. A. King-Hele, Mr. J. T. Smith, Dr. G. Christensen and Dr. D. A. Lavis (mathematics); Mr. P. Wilkes (metallurgy); Dr. J. M. Irvine (theoretical physics); Mr. J. E. B. Ponsonby (radio-astronomy); Dr. R. T. W. L. Conroy (physiology); Dr. A. J. Barson, Dr. A. Garner and Dr. R. S. Kirk (pathology); Mr. G. H. West (polymer and fibre science); Dr. N. Jones and Mr. J. T. Turner (mechanical engineering).

Announcements

Mr. J. H. Nicholas and Mr. M. E. Burt have been appointed deputy chief scientific officers at the Road Research Laboratory: Mr. Nicholas has been appointed head of the Construction Division, and Mr. Burt head of the Design Division.

Mr. H. Ll. D. Pugh and Mr. A. H. Low have been awarded the W. H. A. Robertson Medal and Premium for 1965 by the Council of the Institute of Metals, for their paper, "The Hydrostatic Extrusion of Difficult Metals", which was published in the March 1965 issue of the *Journal of the Institute of Metals*.

The 1966 congress of the Institute of Animal Technicians will be held in the University College of North Wales during March 31–April 1. Further information can be obtained from Mr. A. E. Mundy, 5 Ouse Bridge Drive, Carlton, Nottingham.

The first meeting of the newly formed North East Section of the Society for Analytical Chemistry will be held in Durham on March 24. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

A symposium on "Scottish Estuaries", arranged by the Institute of Biology (Scottish Branch), will be held in the University of Strathclyde during March 31–April 1. Further information can be obtained from Dr. E. J. Perkins, Department of Applied Microbiology and Biology, Biology Annexe, University of Strathclyde, George Street, Glasgow, W.1.

A joint meeting of the North of England Section of the Society for Analytical Chemistry and the Leeds University Union Chemical Society will be held in the University of Leeds on March 18. Prof. C. L. Wilson will deliver a paper on "Analysis Reborn". Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

A conference on "Nuclear Structure and Elementary Particles", arranged by the Nuclear Physics Sub-committee of the Institute of Physics and the Physical Society, will be held in the University of Oxford during March 30–April 1. Further information can be obtained from the Meetings Officer, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A symposium on "Tape Recording of Biological Signals", organized by the Scottish Section of the Institution of Electronic and Radio Engineers and the Scottish Electronics and Control Section of the Institution of Electrical Engineers, will be held in Edinburgh on March 29. Further information can be obtained from Mr. P. M. Elliott, 21 Craigmount Loan, Corstorphine, Edinburgh 12.

NATIONAL RESEARCH DEVELOPMENT CORPORATION

THE sixteenth annual report of the National Research Development Corporation*, covering the year ended June 30, 1965, again emphasizes a marked increase in the Corporation's activities; to cope with the anticipated increase, major changes were made in the organization of the Corporation. The two Departments of Applied Science and Engineering have been divided into groups for Bio-Sciences, Industrial Chemistry and Scientific Equipment, and for Electrical Engineering and Electronics, Computers and Automation, Mechanical Engineering, and Production Engineering, respectively, and a Department of Planning and Policy Co-ordination has been established. Financial assistance was provided for more than thirty-five new projects (representing an initial investment of £5,759,000) compared with thirty in the previous year, as well as additional support of about £2 million for existing projects including hovercraft. Actual expenditure on development was £591,339 compared with £457,366 in the previous year, and forward commitments now amount to £8,653,000. Nine items of development expenditure totalling £128,000 were written off, and ninety-five development projects were in being at the end of the year compared with sixty at the end of the previous year. During the year, fifty-six new licence agreements with firms in the United Kingdom and overseas were completed, and nineteen terminated, compared with seventy-one and thirty-three, respectively, in the previous year, making a total of 593 licence agreements in force in the United Kingdom and 56 overseas (561 and 58, respectively, in the previous year).

Two major changes during the year noted in the report were the transfer in February 1965 of statutory responsibility for the Corporation from the Board of Trade to the Minister of Technology and the extension of the Corporation's financial resources and the increase of its scope under the Development of Inventions Act, 1965, passed in June. The Corporation believes that its future business will continue to be concerned mainly with supporting technological development, but that work of a high-risk, long-term, or applied-research nature will be more extensively supported where this is judged to have a probable commercial advantage for an industrial user. Even more extensive may be the support of innovation in industry, and for this purpose the Corporation's experience in furthering the exploitation of its own projects may be more generally applied. The Corporation also affirms its belief that in all significant developments where Government spending with industry is involved, it has much experience to offer in the conduct of joint ventures with firms. It considers that Government departments could well profit from closer contact between the research establishments and itself. It also believes that further steps should be taken to increase the awareness of industry of the help which the Corporation could give. The report reiterates the view that in future the proportion of projects in which industry and the Corporation share the risks will increase and that a large increase in the number and scope of applications for assistance from industry can be expected.

Of the 1,122 inventions communicated to the Corporation during the year, 276 were from Government departments and Research Councils, 168 from universities, nine from industrial research associations, 93 from private firms and 510 from private individuals in the United Kingdom. Of 183 patent rights assigned to the Corporation during the year, 134 were from Government departments and Research Councils, thirty-four from universities and two from industrial research associations. At the end of the year, the Corporation held 377 United Kingdom patent applications and 817 granted patents, as well as 912 overseas patent applications and 1,346 granted patents. A further 113 United Kingdom patent applications and forty-nine granted patents were held by the Corporation's subsidiary development companies, as well as 443 overseas patent applications and 432 granted patents. The 1,226 United Kingdom patents and patent applications which are the subject of exploitation include some awaiting formal assignment. Receipts from exploitation amounted to £436,853. The Corporation is represented on the Co-ordinating Committee on Technology for Developing Countries and has supported projects intended to meet the specific needs of the developing countries. The Joint Development Committee with the Department of Scientific and Industrial Research no longer exists.

Among new projects started during the year under the Bio-Sciences Group are those for a bollworm attractant, a process for a component of human follicle stimulating hormone, fish-drying equipment, a locust attractant from grass and a typhoid vaccine. Under the Industrial Chemistry Group the report notes new projects for bonded boron carbide, metal polishes and a plastic sealing process; and under the Scientific Equipment Group, for an endo-microscope, a histogram plotter, membranes for heart–lung machines, and a project for a library of teaching programmes on industrial training for use with teaching machines.

The Computers and Automation Group records new projects for the automatic process and plant control system known as *ARCH*, for developing computer hardware and software, and for a magnetic tape recorder and a magnetic tape store. The Electrical Engineering and Electronics Group gives details of new projects for a beta-backscatter gauge and a high-background radiation monitor and reports that the first batch of six instruments for a photosonic blind aid has been completed. Work continues at the Imperial College of Science and Technology on the fundamental aspects of two systems of television bandwidth compression although support from the Corporation was terminated at the end of 1964. New projects in the Mechanical Engineering Group are for the development of a large Diesel engine of advanced and novel (opposed piston) design, and epicyclic gears. The Production Engineering Group reports schemes for a new type of tunnel kiln (hoverkiln) for firing clay and glazed ceramics and pottery, and a numerically controlled turning machine. At the time when the report was published the development and test programme for flexible containers—the *Dracone* project—was almost complete and the original fuel cell programme was expected to be completed by the end of 1965. Satisfactory progress is reported with the oil well drilling rig project, and further progress with the development of hovercraft is also recorded, including the initiation of a joint programme of research at the National Physical Laboratory.

* National Research Development Corporation Sixteenth Annual Report, 1964–65. Pp. 53+8 plates (London: H.M.S.O., 1965) 5s. net

THE LEVERHULME TRUST

THE fifth report of the Leverhulme Trustees* covers the years 1962–64, in which commitments totalled £1,230,950, of which £591,650 was to the universities and centres of higher education, £130,950 to learned societies and research institutions, and £193,700 to medical research; these figures compared with £885,350, £371,150, £46,550 and £184,900, respectively, in the triennium 1959–61. Among the grants to universities may be noted £3,750 to the Department of Zoology, University of Cambridge, for taxonomic work; £11,000 to the Department of Sociology, University of Essex, for a survey of journalism; £1,300 to the University of Keele for research into municipal government; and £18,500 to the University of Lancaster for research into higher education. A further £3,000 went to the University of Leeds for research posts in the history and philosophy of science, and £24,000 for the proposed diploma course in development administration for overseas students. The University of Liverpool received £34,000 for fellowships in general research; the Institute of Education, London, £18,000; the London School of Economics, £12,950 for scholarship and research awards and £2,400 towards a conference on the philosophy of science. The University of Manchester received £2,700 for a research fellowship in the Department of Chemistry on the metabolism and biosynthesis of unsaturated fatty acids, £4,000 for an investigation of income distribution in the United Kingdom before and after tax, and a final grant of £6,000 for the Jodrell Bank Experimental Station. The Department of Chemistry, University of Newcastle upon Tyne, received £3,600 for an investigation of the enzyme, catalase, in the decomposition of hydrogen peroxide, and the University of Nottingham £8,900 for a project in adult education through the medium of television. A grant of £35,000 to Queen's University, Belfast, was for staff for the School of Librarianship, while £11,550 goes to the University of St. Andrews for industrial health courses at Queen's College, Dundee, and £22,500 to the University of Southampton for the Department of Econometrics. Overseas grants included £18,000 for tutorial staff for University College, Dar-es-Salaam; £28,000 for Royal Society Leverhulme visiting professorships for India; £24,500 for the Inter-University Conference, Hong Kong; £15,000 to University College, Nairobi, for adult education; and £18,000 for tutorial staff at University College, Makerere.

The Association of Commonwealth Universities received £6,600 for travel grants for the ninth quinquennial conference, the British Association £3,500 for analysis of mathematics teaching projects, the British Museum £3,500 for a research fellowship on mammals, the Institute for Strategic Studies a further £4,500 for a research assistant, the Joint Mathematical Council for the United Kingdom £6,000 for research into teaching mathematics, and the Institute of Mathematics and its Application another £8,000 for the same purpose. £70,000 went to the Royal Society for Leverhulme Scholarships for young scientists, and £3,000 to the Scott Polar Research Institute for a research assistant.

Awards to schools, chiefly for scholarships, totalled £36,400; to architecture, £48,600, including £9,000 to the Royal Institute of British Architects for an industrialized building study; and miscellaneous grants included £15,000 to the Administrative Staff College, £20,000 to the Centre for Educational Television Overseas for English Language Teaching, £15,000 to Voluntary Service Overseas, and £5,000 to the Overseas Development Institute for an economic survey of Uganda. Among those for medical research may be mentioned £22,500 to the Department of Electrical Engineering, Imperial College of Science and Technology, for a one-year course for post-graduate medical students; £20,000 to the Liverpool School of Tropical Medicine for a visiting lectureship, £25,000 to the Middlesex Hospital Medical School for scholarships at the Institute of Clinical Research; £32,400 to the Eastman Dental Hospital for visiting Indian and Pakistani studentships; £13,500 to the Royal College of Surgeons for research assistantships at the Institute of Basic Medical Sciences; £8,300 to the Institute of Orthopaedics for a research fellowship in the Department of Biomechanics; and £6,600 to the Department of Mental Health, University of Aberdeen.

* The Fifth Report of the Leverhulme Trustees, 1962–1964. Pp. 93. (London: The Leverhulme Trust, 1965.)

SELECTION OF CLAY BUILDING BRICKS

DEFECTS in brickwork, when these occur, are not necessarily due to faulty design or construction, but often probably because the properties of the bricks used in a particular building or other project are not given enough serious consideration in the first place, relative to the proposed conditions which they are destined to withstand. For example, constructional brickwork should not, be or remain, excessively wet, since clay building bricks differ in their tolerance of exposure to wet conditions; wet brickwork lends itself to risk of sulphate attack on the mortar, to efflorescence, and to frost damage; sulphate expansion of mortar rarely occurs except in parapet and retaining walls subject to continual water infiltration; where sulphate expansion of brickwork in normal external walls does occur, this is often due to the bricks themselves containing excessive soluble sulphates, for example, potassium sulphate. This advice is among the many practical hints given in *The Selection of Clay Building Bricks*—1*.

Criticisms are often voiced on the admittedly ugly, white, powdery growth or encrustations revealed on brickwork, especially on new buildings, to the effect that this is due to use of newly manufactured bricks, not properly kilned, or possibly not long enough 'seasoned' or to use of inferior raw materials, and so on; actually, as this pamphlet is at pains to emphasize, efflorescence is normally a temporary springtime occurrence on new brickwork and is generally harmless; it happens because very small amounts of alkali salts, usually derived from cement in the mortar, are latent to produce this blemish given the right conditions. "Examples of destructive efflorescence, where crystallization of soluble salts causes crumbling of brick surfaces or displacement of plaster, are rare—probably rarer than they were a generation ago, to judge from enquiries received at the Building Research Station." Efflorescence can recur every spring for many years, so long as water can find ways of percolating through the brickwork; in parapet walls this often implies faulty damp-proof courses; none the less, it is on all occasions unsightly, but difficult to eradicate completely; beyond remarking that the precautions on site necessary to reduce

* Building Research Station Digest (Second Series), No. 65 (December 1965): *The Selection of Clay Building Bricks*—1. Pp. 4. (London, H.M.S.O., 1965) 4*d*

or avoid efflorescence are tedious and seldom observed in practice, no suggestions are forthcoming on how best to eradicate this trouble; superficially this may be done by various expedients, but the result is seldom permanent, if conditions inside the brickwork are unfavourable or if there is recurrent reaction between water and vulnerable constituents in the cement.

On the question of frost damage to bricks, this appears to be rare in normal external walls between damp-proof course and eaves, although not uncommon in parapets, free-standing walls, and retaining walls, especially where insufficient care has been exercised in selection of special quality bricks. Thermal, and particularly moisture, expansion of bricks are important factors; the former happens with all building materials, its effects are well known and usually allowed for at the design stage; the latter form of expansion is not so generally recognized, this property only receiving scientific attention in recent years. The practical implications of moisture expansion, as set forth in this publication, may be summarized thus: bricks should not be used straight from kiln, or on site unless stacked for at least one week; special attention must be paid to storage before use if bricks are to be laid in high-strength mortar, which will become rigid very quickly; short returns in brickwork, specially vulnerable to cracking by expansion, are to be avoided; in long walls, expansion joints should be provided capable of accommodating an expansion of $\frac{3}{8}$ in. in 40 ft. Quality control testing of bricks, envisaged in the new British Standard 3921 : 1965, is here strongly and rightly urged; acceptance of 20-year-old test reports, still occasionally proffered by manufacturers of bricks, should be refused.

MINERALS OF THE SEA

A SURVEY and understanding of the geology of the sea-floor, implying the four oceans and the shallower seas that feed them, equally a knowledge of the organic and inorganic constitution of sea-water itself, are not new concepts in the realms of exploration or exploitation of the resources of the Earth, but much more is to-day being heard and learnt of this fascinating subject because of the universally intensified research efforts being made in its contemporary study. From the original *Challenger* expedition to the present *Mohole* project, the story of the oceans and that greater part of the Earth's crust which they conceal, has been slowly but very surely growing. Scientific interest, in stature, far outweighs that of economic, commercial investigations into the problems of the oceans, but that state of things is probably destined to be upset, if not reversed, in the not-too-distant future. All over the world the energy, food and mineral resources of the oceans are being re-appraised, explored and, where feasible, exploited in the interests of mankind. Britain is by no means behind in the quest, and this does not mean simply 'North Sea oil and gas prospects'.

In September 1965 there began a relatively little publicized investigation into the possibilities of long-term exploitation of the oceans and their resources, sponsored by the Commercial Oceanology Study Group, a consortium of six British companies: British Petroleum, Richard Costain, Hawker Siddeley Group, Imperial Chemical Industries, Rio-Tinto Zinc Corporation, and Unilever. This joint project is expected to last at least a year. According to an article entitled "Minerals of the Sea" (*BP Magazine*, No. 17; Autumn 1965. The British Petroleum Co., London), each company is already working in different but related fields of oceanology; each will ultimately contribute its own particular knowledge and experience to the study. The article itself is an extract from the book, *World Beneath the Oceans*, by Dr. T. F. Gaskell (courtesy of Aldous Books, London, 1965); Dr. Gaskell, with Mr. D. C. Ion, both of British Petroleum, are members of this Study Group.

This particular article is devoted specifically to the minerals of the sea, the salts it carries and deposits, and the natural cycle of meteorological and geological events which, through millions of years of time, have given rise to them. Salinity measurements through the entire width and depth of the oceans have been going on during the past eighty years or so, and the chemical composition of sea-water is well established; the problem is, how are we going to extract or mine some of the more valuable products it contains on an economic scale? As Dr. Gaskell rightly points out, shortage of terrestrial fresh-water, as world population increases, must inevitably be made good by water processed from the sea; in fact, water will become one of the most important products of the sea. Other examples are magnesium (there are 4 million tons of magnesium dissolved in every cubic mile of sea-water), for which the process is already perfected; bromine, for the photographic industry and for producing anti-knock compounds for petrol; gold, the pipe-dream of men for years past: ". . . there is more gold in the sea than there is in use now", but commercially this problem has not yet been solved. Iodine is obtained from plants and animals of the sea; lobsters collect cobalt; the oyster gathers stray atoms of copper; and so on. The origin of petroleum, actually still an unsolved mystery, is in modern theories intimately bound up with the sea; sooner or later this secret will be unfolded, perhaps when we know more about the ocean floor itself.

THE MOLE: ITS ADAPTATION TO LIFE UNDERGROUND

THE increased economic importance of the mole (*Talpa europaea*) as a farm pest has engendered renewed research into its behaviour and structure. The Ciba Foundation guest meeting on "The Mole: its Adaptation to an Underground Environment", held on January 5 and 6, was attended by approximately thirty persons and eleven papers were contributed covering a wide variety of topics. There were also several films, tape recordings and demonstrations, providing a very varied programme.

The first day of the meeting was mainly concerned with behaviour. At the beginning of the symposium the mole was considered to be almost exclusively subterranean, continually burrowing in search of food. By the end of the meeting this picture had changed greatly. Dr. K. Mellanby showed that different moles used established burrows over and over again. Natural flooding proved that they could migrate over considerable distances and return after flood waters had receded. Mr. A. T. B. Rudge had succeeded in developing a trap for catching live moles. He had constructed monitored artificial burrows of wire mesh and shown that moles had periods of activity lasting 2–3 h, followed by rest periods of 3–4 h. This rhythm continued day and night. These findings were confirmed in the field by tagging moles with radioactive silver or cobalt sources attached to their tails. In their active periods they were continually running along their burrows (maximum speed up to 2·5 m.p.h.), only stopping for food that had fallen by chance into their runs. Moles did not often tunnel except while making

repairs. Mr. P. Morris showed, by investigating food taken by various animals (for example, species of owls), that moles must often come to the surface, probably mostly at night, to be caught by these predators. Other investigations in France under freak drought conditions gave supporting evidence, as many moles were caught in traps placed on the ground surface. Dr. F. Raw gave details of the food theoretically available to moles. Earthworms, wire-worms, molluscs and insect larvae seemed to form the possible basic diet. Mr. D. W. Yalden finished the day's session by describing the skeletal adaptations to locomotion. The session on behaviour thus presented a very different view of the behaviour of the mole to that normally assumed. It habitually uses preformed tunnels, during its waking periods it is continually searching for food, which it finds by chance encounter as it moves through its tunnels, and it is occasionally a surface dweller, probably mainly at night.

The second session, on microscopy, began with an account of the mole's pituitary gland by Prof. R. L. Holmes, who showed that there were no basic differences from the pituitary gland of other animals. The senses of the mole were described by Dr. T. A. Quilliam. The eyes had a very small number of receptor elements and there was a cellular lens. The mole had a snout packed with Eimer's organs that probably served for tactile reception. There were also innervated vibrissae around the snout and in the tail. The ear was little different to that in other animals, although there were less than two turns to the cochlea. The fine structure of the olfactory mucosa was considered by Dr. P. Graziadei. He showed that the olfactory mucosa was large in extent (as were the olfactory bulbs of the brain). The receptor cells were ciliated, although some of these cells bore only one cilium and were not so closely packed together as in other mammals. The mucosa contained more supporting cells. Drs. R. Lund and J. Lund considered the central visual pathways and showed that they were poorly developed although moles could be taught to discriminate between light and dark. Dr. B. H. Crawford outlined physical methods that were available to investigators to allow recordings to be made in the mole's tunnel, of light, sound, vibrations, heat and some other modalities, to see what sensory clues of the surroundings were available. Dr. M. Lobban outlined her studies on Arctic coal-miners and explained how the circadian rhythms were affected by the unnatural conditions under which the men work, in some ways analogous to those experienced by the mole. She pointed out that moles would be very useful animals for investigation of circadian rhythms. It seemed from the papers in this section that the mole has eyes that have little discriminatory abilities, a very well-developed olfactory sense, an auditory sense and complex tactile receptors in the vibrissae and in Eimer's organs in the snout. Whether the latter organs could detect other environmental features was left uncertain.

The symposium is eventually to be published in full as a supplement to the *Journal of Zoology, Proceedings of the Zoological Society of London.*

SCATTERING OF ELECTROMAGNETIC WAVES BY ELECTRO-ACOUSTIC PLASMA WAVES

By P. F. LITTLE and S. M. HAMBERGER

U.K. Atomic Energy Authority Research Group, Culham Laboratory, near Abingdon, Berkshire

THIS article reports some preliminary measurements of the scattering of an incident beam of microwaves by self-excited plasma waves in a mercury arc column; from these results we derive an experimental dispersion curve for the plasma waves which we compare with a dispersion curve measured directly with Langmuir probes in the column. In this manner we identify the waves responsible for the scattering as propagating electro-acoustic waves, which are known to be present in the positive column of low-density arcs. Both self-excited and externally excited waves of this type have been observed[1,2]. Their phase velocity is approximately $c_s = (KT_e/M)^{\frac{1}{2}}$, where KT_e is the electron thermal energy and M the ion mass: in our plasma $c_s \approx 10^5$ cm/sec.

Let us write for the incident electromagnetic wave the frequency and wave vector ω_1 and $\mathbf{k}_1$; the fluctuations in plasma density may be represented by a spectrum of

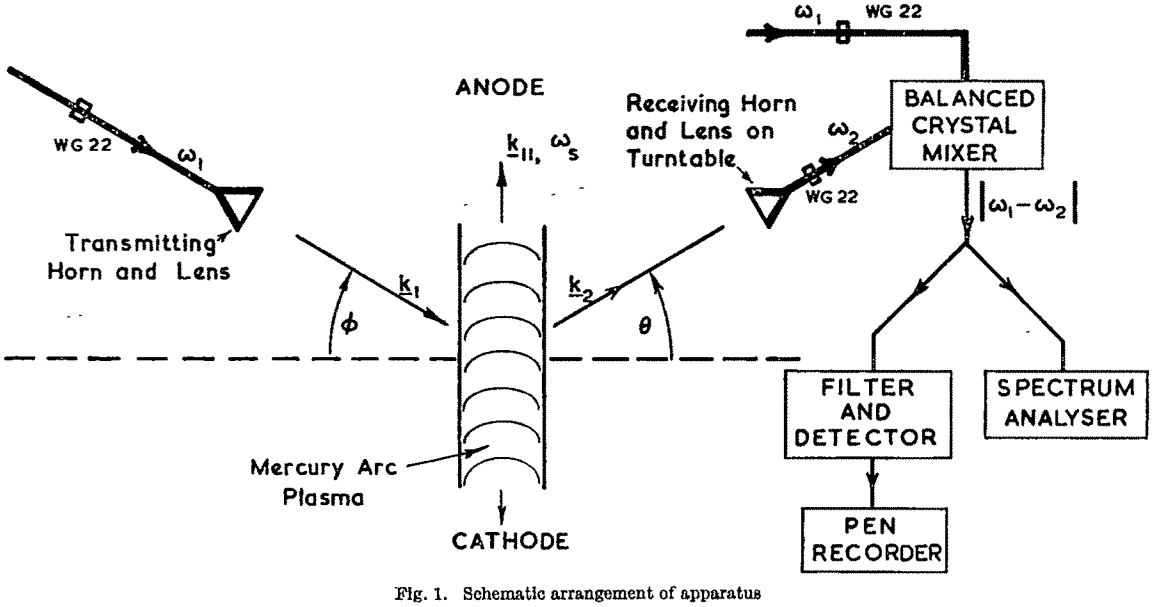

Fig. 1. Schematic arrangement of apparatus

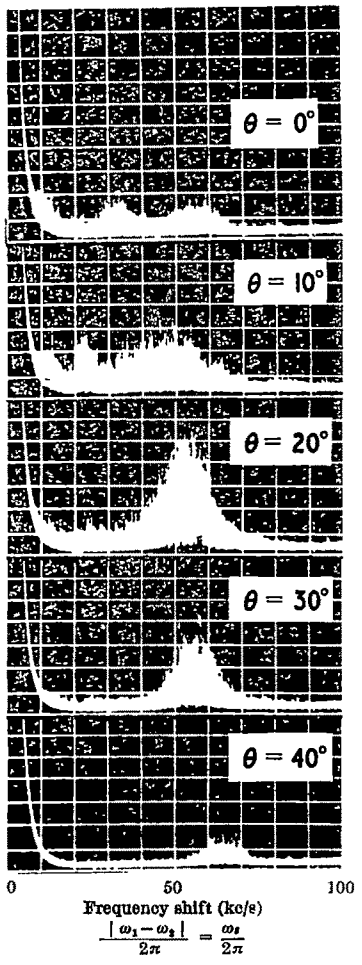

Fig. 2. Spectrum of scattered radiation. Each photograph consists of twenty superimposed traces showing the scattered intensity as a function of frequency shift. The sequence shows how the received spectrum depends on the angle of observation θ for φ = 0

frequencies ω_s and wave vectors $\mathbf{k}_s$. Then, as a result of non-linear interactions in the plasma, the scattered microwave spectrum will be described by typical quantities ω_2, $\mathbf{k}_2$ such that

$$\omega_1 \pm \omega_s = \omega_2 \quad (1)$$

$$\mathbf{k}_1 \pm \mathbf{k}_s = \mathbf{k}_2 \quad (2)$$

From equation (1) we may equate the frequency shift $|\omega_1-\omega_2|$ on scattering to the scattering frequency ω_s. From equation (2) we would expect the scattered wave observed at a particular angle to be due to a particular value of $\mathbf{k}_s$. More specifically, since we are interested in $k_{\|}$, the component of $\mathbf{k}_s$ along the column, equation (2) becomes (see Fig. 1):

$$k_1 \sin\varphi \pm k_2 \sin\theta = k_{\|}$$

or, since $k_1 \approx k_2 = 2\pi/\lambda_0$, where λ_0 = free space wavelength of the incident waves:

$$k_{\|} = \frac{2\pi}{\lambda_0}(\sin\varphi \pm \sin\theta) \quad (3)$$

In our experiment the plasma was the column of a 5-cm-diameter low-pressure mercury arc, as previously described[1], which was operated at 9-amp discharge current and a pressure of 0·4 mtorr. A beam of millimetre microwaves (λ_0 = 8·65 mm) at a power level of a few mW was used to illuminate a short section of the arc (Fig. 1). The receiver could be oriented to observe the same section from different angles. A single klystron provided both the probing signal and the local oscillator drive to the balanced mixer, the output of which therefore consisted of a signal at a frequency $|\omega_1-\omega_2|$, that is at ω_s, which could be observed directly with a low-frequency spectrum analyser.

Fig. 2 shows the spectrum analyser display of the amplitudes of the various frequency-shifted components of the scattered radiation at several different angles to the column, when illuminated at normal incidence (φ = 0). It is obvious from the sequence of spectra shown that there is a large signal around 52 kc/s which has a maximum intensity when the scattering angle θ is about 20°. To obtain a more accurate measure of the optimum scattering angles for a wide range of frequencies ω_s the mixer output was passed through a filter, rectified, and plotted on a chart recorder, while the angle θ was varied between +30° and −50° by rotating the receiver on a turn-table driven by a synchronous motor. Disregarding some spurious maxima associated with the optical system (which did not change with the selected frequency) a maximum or sometimes two maxima corresponding to the ± signs in equation (3) could be found for each frequency in the range 20–70 kc/s. Fig. 3 shows the result obtained for a filter tuned to accept 50 kc/s. From values of θ corresponding to the maxima the values of $k_{\|}$ were calculated from equation (3). The results are shown as a dispersion plot in Fig. 4 for normal incidence (φ = 0) and for φ = 20°.

For comparison we also give in Fig. 4 the measured values of ω_s and $k_{\|}$ for electro-acoustic waves excited in the same plasma by an external coil and detected by a Langmuir probe[3]. A third independent set of observations is obtained by applying the correlation technique used with photomultipliers in earlier work here[1] to the signals from two Langmuir probes, one fixed and one moving. This is an analysis of self-excited waves in the column, leading to the results shown. Within the limits of experimental accuracy all the points lie on a common curve except those for microwaves incident at φ = 20°. For these the dispersion plot appears to be displaced by a small systematic error possibly due to refraction at the tube walls.

Using the theory of Woods[4] and the measured electron temperature, $KT_e = 3{\cdot}4 \pm 0{\cdot}2$ eV, we derive the theoretical dispersion curve for the (0,1) mode shown in Fig. 4. It is in excellent agreement with observation at low frequencies, but at higher frequencies lies above the experimental values, as previously reported[3].

It should be noted that a small but finite value of $k_{\perp}$ is essential to satisfy equation (2) with this experimental arrangement unless φ = θ. The finite size of the plasma alone makes $k_{\perp} \neq 0$, and in addition the wave fronts of

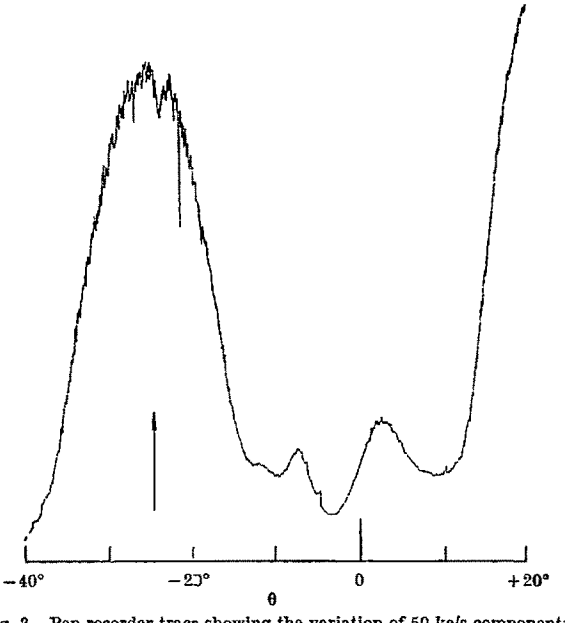

Fig. 3 Pen-recorder trace showing the variation of 50 kc/s components of the mixer output with angle of observation θ. The peak at θ = −24° corresponds to a value of $k_{\|}$ = 2·9 cm^{-1}. The structure at θ = 0° appears at all frequencies and is attributed to geometrical effects

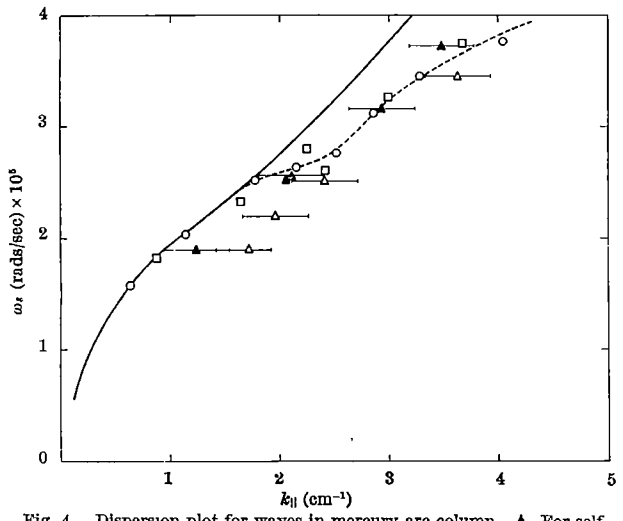

Fig. 4. Dispersion plot for waves in mercury arc column. ▲, For self-excited waves using microwave scattering $\varphi = 0$; △, for self-excited waves using microwave scattering $\varphi = 20°$; □, for self-excited waves using Langmuir probes; -○-, for externally-excited waves using Langmuir probes; —, theoretical curve for (0,1) mode, KT_e = 3·4 eV

the acoustic waves are curved[3]. A range of $k_{\perp}$ values, different for each frequency ω_s, is needed to describe such waves. Hence values of $k_{\perp}$ to satisfy equation (2) can always be found.

These experiments depend on non-linear interaction between certain plasma waves and electromagnetic radiation leading to a frequency-shift on scattering. Other experiments demonstrating this effect have been reported[5]. However, our studies of the angular dependence of the scattered wave intensity provide information also about the wave-length spectrum in the plasma, thus enabling us to identify the scattering wave. This non-perturbing technique may find application in other plasmas.

Such observations of coherent scattering should be contrasted with those in the ionosphere: there the scattering results in a continuum of frequency shifts (line broadening) rather than the appearance of satellite lines. The reason is that acoustic waves in the ionosphere are highly damped, since $T_e \sim T_{ion}$, and the amplitudes of a wave-vector k_s vary stochastically, rather than harmonically, with time[6]. The result is incoherent rather than coherent scattering. On the other hand, electron plasma oscillations at ω_p should lead to satellites at a frequency $\omega_1 \pm \omega_p$, but these have not as yet been observed. We thank Mr. H. G. Jones for valuable assistance with the experimental work.

DETECTION OF CIRCULAR AND LINEAR POLARIZATION IN THE OH EMISSION SOURCES NEAR *W3* AND *W49*

By Dr. R. D. DAVIES, G. DE JAGER and Dr. G. L. VERSCHUUR
University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank

FOLLOWING the detection of anomalously excited OH emission at 1,665 and 1,667 Mc/s from the vicinity of several thermal radio sources by Weaver, Williams, Dieter and Lum[1], Weinreb, Meeks, Carter, Barrett and Rogers[2] reported observations of linear polarization in the 1,665-Mc/s spectrum of the OH source near *W3*. Zuckerman, Lilley and Penfield[3] were unable to detect any linear polarization greater than 8 per cent in two of the features in the spectrum of *W49*.

Prior to the publication of these results a search was begun at Jodrell Bank for the linearly and circularly polarized emission which might be expected from the Zeeman splitting of the narrow lines at 1,665 Mc/s emitted from *W3*, *W49*, *W51* and Orion *A*. The small width of the lines is ideally suited to this search. The present article reports the detection of strong circular polarization in the spectra of the OH sources near *W3* and *W49*.

The narrow band six-channel receiver designed for hydrogen line Zeeman measurements was used for this experiment. The crystal filters have a bandshape equivalent to a gaussian with a half-intensity width of 0·60 kc/s. The receiver has a parametric amplifier front-end which gives an overall system noise of 280° K. For polarization measurements the 250-ft. Mark I telescope was slightly under-illuminated by a crossed dipole and reflector combination. The signals from the dipoles were combined through appropriate line lengths and a hybrid to give either both planes of linear polarization or both senses of circular polarization. The receiver was then switched between the two linear or the two circular polarizations by a diode switch. The output of each of the six channels was recorded on punched tape as the sum and the difference of the two polarized intensities.

A separate investigation was made of the extent and position of the OH sources near *W3* and *W49* using a rather narrower beam obtained with a dipole and shaped reflector plate on the 250-ft. radio telescope. The beam-width in this case was 15′ arc. This investigation confirmed that the OH source was significantly displaced from *W3* in the position $\alpha = 2\text{h } 23\text{m } 29\text{s}$, $\delta = +61° 38'$ (1950·0) given by Weinreb, Meeks, Carter, Barrett and Rogers. The OH source in *W49* coincides in position with the low right ascension component of *W49* as found by Zuckerman, Lilley and Penfield.

The *W3* Source

The OH source near *W3* has a simpler emission spectrum than that of *W49* and the preliminary results of the investigation to be reported here will be largely concerned with the former source. Fig. 1*a* shows the main emission features in the spectrum of the source near *W3* plotted as the mean of the opposite senses of polarization. This spectrum shows much detailed structure, some of which is very narrow. The feature at −8·5 kc/s and the sharp edges at −1·5 kc/s and +8·5 kc/s indicate root mean square velocity spreads of 0·10, 0·09 and 0·08 km/s. The narrow structure is also reflected in the circular polarization data.

The difference between left- and right-hand circular polarization intensities is plotted in Fig. 1*b*. The sense of polarization is that seen when viewed along the direction of propagation. Strong circular polarization effects are evident over the whole emission spectrum. The data have been corrected for systematic effects amounting to 10 per cent of the profile intensity which had been carefully measured in separate observations of strong radio sources. It is believed that Fig. 1*b* represents the true circular polarization intensity to better than 10 per cent of the

profile intensity. The peak-to-peak noise on the plot is ±1° K. The circularly polarized components at −19·5 kc/s, −8·5 kc/s and +7 kc/s are nearly 100 per cent polarized. The most intense circularly polarized feature at −0·5 kc/s lies on the low-frequency side of the main emission peak of Fig. 1*a* and indicates 60 per cent circular polarization at this frequency. In the frequency interval +1 kc/s to +6 kc/s the polarization structure is complex and indicates the presence of several polarization features. Similarly, in the range −24 kc/s to −2 kc/s there is a low, but significant, level of circularly polarized structure.

Linear polarization measurements were made at three selected feed angles at which systematic effects were less than 10 per cent. Observations at different hour angles provided a range of position angles (pa) to give a measurement of the polarization temperature and position angle every 0·5 kc/s throughout the spectrum. These results are shown in Figs. 1*c* and 1*d*. Significant linear polarization effects are observed in regions within the spectrum. A maximum polarization temperature of 5° ± 2° is observed at the centre of the strong line at +0·5 kc/s corresponding to 25 ± 10 per cent polarization. The features at −8·5 kc/s, −3·5 kc/s, +6 kc/s and +21·5 kc/s also show significant polarization effects. On the other hand, features such as those at −6 kc/s, −2·5 kc/s, +3·5 kc/s and +8 kc/s show linear polarization temperatures less than ~1° K which for these features corresponds to <30, <12, <15 and <12 per cent polarization, respectively. The position angle remains constant over most of the linearly polarized features except in the case of the region from −1·5 kc/s to +2·5 kc/s which shows a gradual variation from position angle = 55°–120°. This result should be taken into account in any interpretation of the data. There appears to be general agreement between the present results and the more limited linear polarization data published by Weinreb, Meeks, Carter, Barrett and Rogers[2].

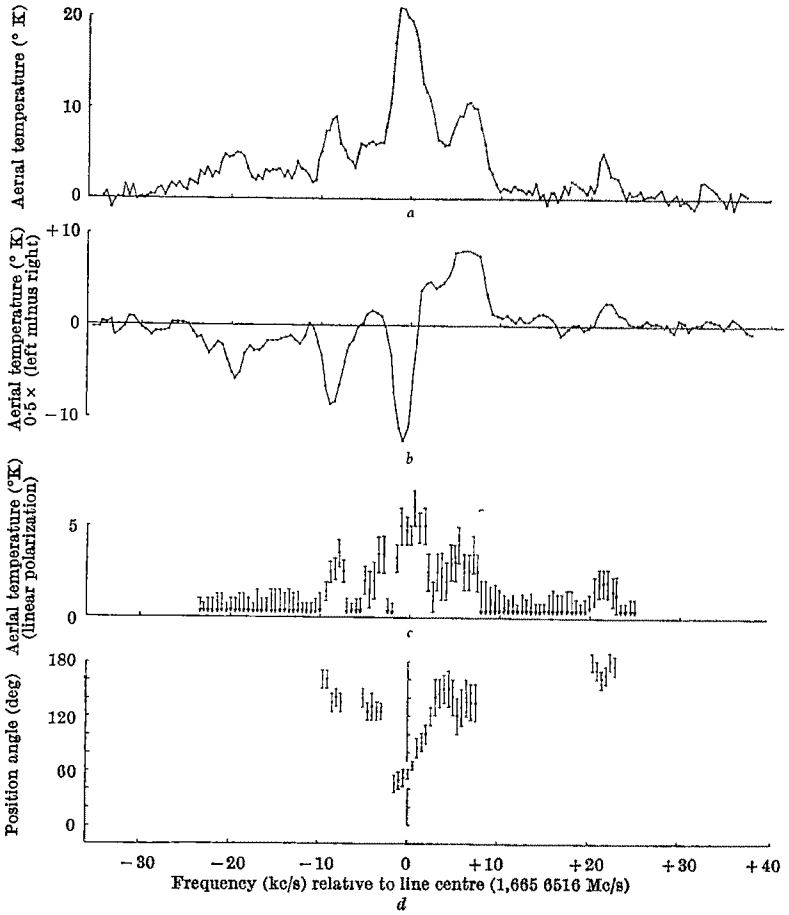

Fig. 1. Observations of the OH emission source near *W*3. *a*, The emission spectrum. The frequency is given relative to the centre of the main feature at 1,665·6516 Mc/s. This spectrum is the mean of the orthogonal polarization intensities. *b*, The difference in intensity between left- and right-hand circular polarization. *c*, The intensity of linear polarization measured as the amplitude of variation of intensity with position angle (equals 0·5 (*T* max–*T* mn)). The errors indicated are ~1 *S.D.* Systematic effects which would double these errors are probably present. *d*, The position angle of the linearly polarized component

The W49 Source

Extensive circular and linear polarization measurements were also made of the 1,665-mc/s emission from the OH source near *W*49. Because of the more complex spectrum of this region, only preliminary results will be reported here. They indicate polarization phenomena very similar to those found in *W*3. The major difference between the two OH sources is that the broad central complex of *W*49 shows rather weaker polarization effects. The emission spectrum and the difference between left- and right-hand circular intensities are shown in Figs. 2*a* and 2*b*.

In the *W*49 OH source the component at −116 kc/s is strongly circularly polarized. Narrow polarization components can be distinguished in the central complex. Linear polarization measurements show that the features at −116, −99 and −94 kc/s are less than 20 per cent polarized.

Interpretation of the Results

With the detection of strong circular polarization in the emission spectra of the *W*3 and *W*49 OH sources it would seem reasonable to look first for an explanation of these effects in terms of the Zeeman effect. Zeeman splitting is possible in the four hyperfine splitting lines of the $^2\pi_{3/2}$, $J = 3/2$ Λ doublet state of ^{16}O ^1H centred around 1,666·3 Mc/s. In the case of the 1·665 Mc/s line the Zeeman splitting is 1·17 $\mu_0 H$, where μ_0 is the Bohr magneton. This corresponds to a splitting between the σ components of 3·3 kc/s for 10^{-3} G. For a magnetic field directed away from the observer the right-hand circularly polarized component is displaced to a lower frequency in an emission spectrum. The observations will now be discussed in terms of a possible Zeeman effect.

The relatively simple emission spectrum of the OH source near *W*3 is split into a rather complex pattern of circularly polarized components. It can be shown that the components in Fig. 1*b* can be arranged into pairs of oppositely polarized σ components. Moreover, within the limits of errors of the results the intensity of left-hand circular polarization integrated over the entire spectrum is equal to the intensity of right-hand circular. This is as expected for the Zeeman effect.

The linear polarization data should be compatible with the circular polarization results, having σ components at the same frequencies as the circular σ components. In addition the linearly polarized components for a single feature should have a constant position angle with a sharp 90° position angle break between the π and σ components. Such a sharp position angle step is seen in Fig. 1*d*. However, as already noted in the range −1·5 kc/s to +2·5 kc/s, there is a gradual change in position angle. Such an effect would result from the addition of the linearly polarized Zeeman patterns of two distinct features which were phase coherent; alternatively the result is consistent with an additional component at 1·5 kc/s. Indeed, in this region of the spectrum the circular polarization data also require more than

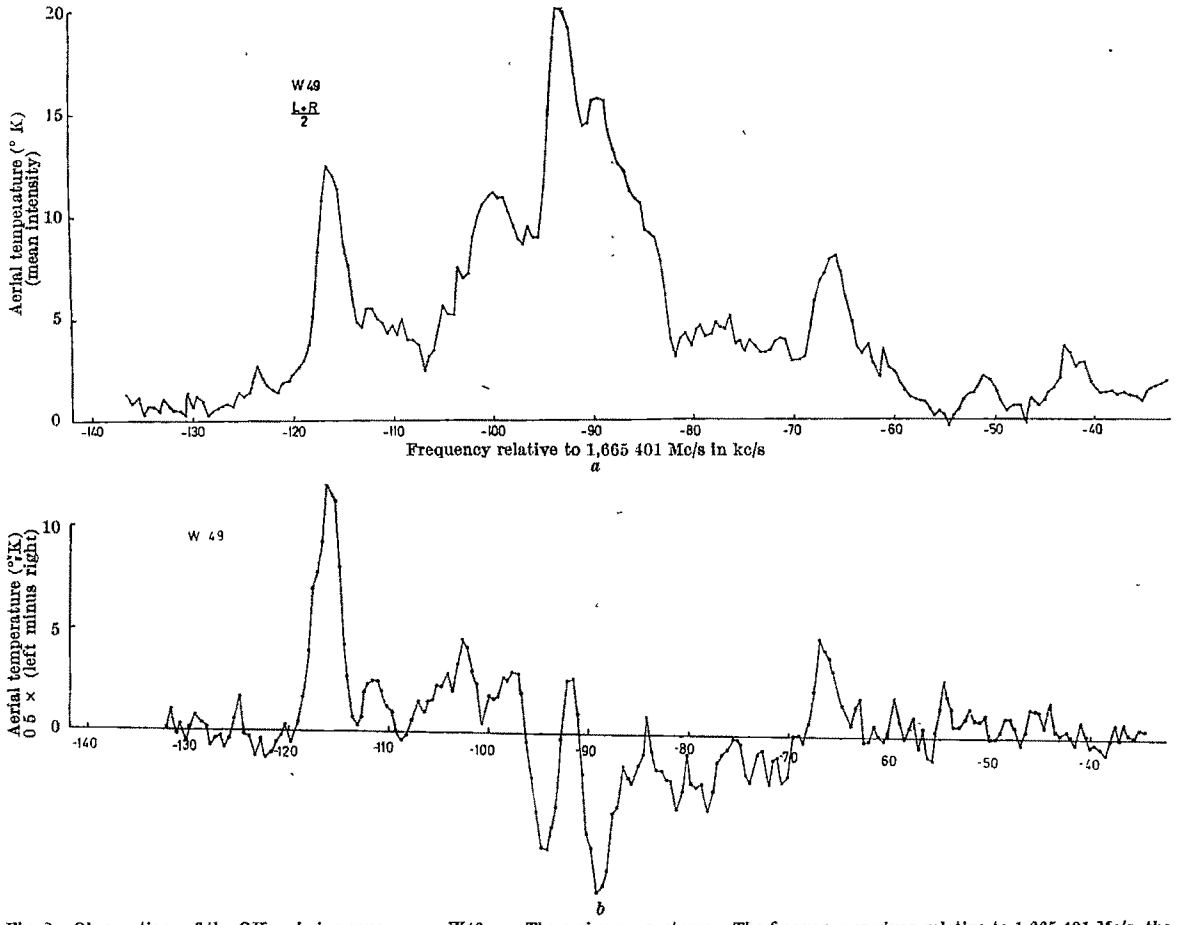

Fig. 2. Observations of the OH emission source near *W*49. *a*, The emission spectrum. The frequency is given relative to 1,665·401 Mc/s, the rest frequency. The spectrum is the mean of the opposite senses of circular polarization. *b*, The difference in intensity between left- and right-hand circular polarization

one Zeeman-split feature. As would be expected with the Zeeman effect, the features which show the largest percentage circular polarization (for example, −19·5 kc/s, −9 kc/s, +8 kc/s) show little or no linear polarization. Moreover, in a complex of features with overlying π and σ components the smaller (by half) frequency separation of the linearly polarized components will result in a greater cancellation of the linear polarization than the circular polarization.

The complete resolution of the circular and linear polarization data on the basis of Zeeman splitting into features with varying but related amounts of linear and circular polarization has not yet been made. However, a first attempt shows that the stronger components can be fitted to a self-consistent Zeeman pattern. A solution is suggested in Table 1. Other combinations of fields may possibly be fitted to the data particularly for the weaker features listed under *D*. A good agreement in the direction of the magnetic field is indicated by the results of Table 1. All features show that the major component of

Table 1

σ	π	σ

the field is directed away from the observer. Even if *D* is taken as two features, corresponding to about half the field strength so that the other σ components lie in the complex near 0 kc/s, the fields in both would again be directed away from the observer. The magnetic field in features *A* and *C* is closely aligned in the line of sight. In feature *B* the field is inclined at 30° to the line of sight and its projection on to the plane of the sky lies at position angle 50°. The field in feature *D* is also inclined at about 30° to the line of sight and its projection on to the sky lies at position angle 85°.

Conclusion

The foregoing considerations indicate that it is possible to interpret the present circular and linear polarization data as a Zeeman splitting of the OH emission line. The magnetic fields so derived for the *W*3 OH emission source are extremely high in comparison with the fields believed to exist in the galactic plane as investigated, for example, in normal interstellar neutral hydrogen clouds (see, for example, Davies, Shuter, Slater and Wild[4] and Verschuur and Davies[5]) which are at least 10^2–10^3 times weaker. The circular polarization results for *W*49 would indicate similar magnetic field strengths.

The present observations clearly demonstrate the existence of strong circular polarization in the anomalous OH emission spectrum at 1,665 Mc/s from the OH sources near *W*3 and *W*49. If the interpretation of the data in terms of the Zeeman splitting suggested here is correct, then unexpectedly large magnetic fields are involved which raise many problems in connexion with the OH lines requiring further discussion.

We thank Prof. A. G. Gaydon, of the Imperial College of Science and Technology, and Dr. A. E. Douglas, of the National Research Council of Canada, for indicating the

structure of Zeeman splitting expected for the OH lines. Dr. H. E. Radford supplied us with exact values of the Zeeman splitting. Dr. R. J. Long and D. Williams assisted with the modification and testing of the feed system for this experiment. We also thank Sir Bernard Lovell for his interest and encouragement in this project.

TRITERPANES IN OPTICALLY ACTIVE PETROLEUM DISTILLATES

By I. R. HILLS and E. V. WHITEHEAD
British Petroleum Co., Ltd., Sunbury-on-Thames, Middlesex

THE identification in petroleum of two isoprenoid hydrocarbons, phytane and pristane[1,2], lends additional support to the theory that petroleum, like coal, is derived from a biological source material. Further support for this theory springs from the knowledge that certain petroleum distillates[2,3], and some from coal[4], are optically active. In each case this activity has been associated with saturated polycyclic hydrocarbons, and the frequent occurrence of optical activity in biochemical systems is well known. Several authors[5–7] have suggested that these polycyclic hydrocarbons might be derived from naturally occurring steroids and triterpenoids.

We have examined distillates, boiling in the range 340°–550° C (taken under reduced pressure so that the temperature of the sample being distilled did not exceed 300° C), from several crude oils and have paid particular attention to such distillates from Nigerian crude oil. The specific rotation of these Nigerian distillates increases from $(\alpha)_D^{19}$ + 1·08° at boiling-point 410° C (at 760 mm, corrected) and reaches a maximum $(\alpha)_D^{19}$ + 6·9° at boiling-point 478° C. After this, the activity diminishes progressively until distillates boiling at about 500°–550° C show only marginal activity; $(\alpha)_D^{19}$ + 0·3°.

A detailed examination of the Nigerian distillate boiling at 340°–480° C was carried out, and liquid adsorption chromatography over silica gel yielded 71–72 per cent by weight of a naphthene plus paraffin portion. Mass spectra indicated the presence of high concentrations of the hydrocarbon series C_nH_{2n-6} and C_nH_{2n-8}, with carbon numbers in the range C_{27} to C_{31}, and a prominent fragment at *m/e* 191. Half this saturate concentrate formed an adduct with urea, and 66 per cent by weight of the adducted hydrocarbon proved to be *n*-alkane (*n*-C_{19} to *n*-C_{34}). The remaining 34 per cent of adducted hydrocarbon appeared from gas-liquid chromatograms to be mainly 2- and 3-methylalkanes[8].

Thermal diffusion[9], in two stages, of the urea non-adduct yielded two materials [$(\alpha)_D^{18·7}$ + 17·6° and $(\alpha)_D^{20}$ + 14·5°, in cyclohexane, respectively]. These materials were combined and, after a preliminary separation by liquid-adsorption chromatography over alumina, yielded a resin (approximately 1 per cent weight on the crude oil). A portion of the gas-liquid chromatogram of this resin (later shown to be a concentrate of pentacyclic naphthenes) is reproduced in Fig. 5. Prominent peaks are lettered and the hydrocarbons eventually isolated from this resin are in turn lettered so that they are equivalent to the corresponding peaks in the gas-liquid chromatogram. This resin was re-chromatographed over alumina to give sixteen fractions. Fraction 3 (0·4072 g), after crystallization from a variety of solvents, yielded 5 mg of hydrocarbon '*F*' (purity by gas-liquid chromatography > 98 per cent weight, melting-point 232·5°–234·5° C corrected) and eventually 1–2 mg of hydrocarbon '*D*' (purity > 90 per cent, melting-point 169°–180° C corrected). Fraction 9 (0·1790 g) likewise yielded some 2–3 mg of hydrocarbon '*E*' (purity > 98 per cent, melting-point 259·5°–260·5° C corrected). The analytical data determined on the three solid hydrocarbons are listed in Table 1. There was unfortunately an insufficient sample for the determination of the optical activities of the two pure hydrocarbons '*E*' and '*F*', or of '*D*'. The analytical data, included in Table 1 and discussed briefly below, suggest that these are pentacyclic triterpanes (the term triterpane has been used to denote the fully saturated hydrocarbon analogues of the triterpenes). High resolution mass spectrometry (Associated Electrical Industries '*M.S.* 9') confirmed an increase in concentration of the hydrocarbon series C_nH_{2n-8} at C_{27}–C_{31} in the resin from thermal diffusion. Prominent fragments in the mass spectrum at *m/e* 205, 177, 137, 123 and 109 were now dominated by the very intense fragment at *m/e* 191. Djerassi *et al.*[10] note the frequency with which this fragment at *m/e* 191 occurs in the mass spectra of triterpanes. In the mass spectrum of lupane two different fragment species contribute to this peak at *m/e* 191 making it by far the most intense fragment in the upper part of the spectrum. One of these species, which contains rings *A* and *B*, is classed by these authors as the most characteristic fragmentation product of pentacyclic triterpanes. The mass spectra of our hydrocarbons '*D*', '*E*' and '*F*' are compared with that of authentic lupane in Figs. 1–4. These are seen to be similar; each contains a strong parent peak, *M*, and a significant peak at *M*-15 as well as prominent fragments at *m/e* 191, 137, 123 and 109. Hydrocarbon '*D*' shows in addition a strong peak at *m/e* 177. The accurate masses of the molecular ions (listed in Table 1) indicate that hydrocarbons '*E*' and '*F*' each contain five saturate rings and thirty carbon atoms, and a molecular skeleton based on perhydropicene is thus one of the types which must be considered.

The infra-red spectra of the resin (obtained by thermal diffusion of the urea non-adduct), and the hydrocarbons '*E*' and '*F*' isolated from it, were very similar to that of lupane. The spectra demonstrated that these materials were free of hydroxyl, carbonyl and double bonds.

Authentic lupane exactly reinforces peak *J* shown in the gas-liquid chromatogram (Fig. 5) and the possible identity of *J* with lupane cannot be excluded at this stage. All of the triterpanes that we have examined (zeorinane, friedelane, heterolupane and γ-onocerane) have retention volumes which occur in the region covered by peaks *C*–*P* in the gas-liquid chromatogram, but none of these reinforces any of the peaks in the chromatogram. The presence of a peak at *I* in Fig. 5 is not obvious, but one was discovered between peaks *E* and *D*, when the chromatograms of the sixteen fractions separated by liquid adsorp-

tion chromatography over alumina; as already described, were examined.

The nuclear magnetic resonance spectra of hydrocarbons '*E*', '*F*' and lupane are all very similar and each contains eight methyl groups per molecule (Table 1).

Hydrocarbon '*E*' is being examined by X-ray crystallography. Measurement of the unit cell dimensions and density gave a molecular weight for '*E*' of 411, in good agreement with the value determined by mass spectrometry (Table 1). Inspection of the Patterson syntheses and the Fourier maps suggests a nucleus, probably based on perhydropicene, in which four of the five rings (*A*, *B*, *C*, *D* or *B*, *C*, *D*, *E*) are clearly seen to be six-membered. The conformations of these four rings are all chair and the ring fusions are all *trans*. The conformation of the fifth ring is not yet fully established nor are the locations of all of the eight methyl groups. The detailed structure of hydrocarbon '*E*' will be published elsewhere when the X-ray investigations are complete.

The cumulative evidence leaves little doubt that hydrocarbons '*E*' and '*F*' are pentacyclic triterpanes. From the scanty data so far obtained, '*D*', with five rings and twenty-nine carbon atoms (Table 1), would appear to be a *nor*triterpane.

The occurrence of these triterpanes is not limited to Nigerian crude oil. Similar resins from Kuwaiti, Iranian and Libyan crude oils yield gas-liquid chromatograms with the same peaks *A*–*D*, *G*–*H* and *K*–*P*, but the proportions in each crude are different. The peaks *E*, *F*, *I* and *J*, prominent in the gas-liquid chromatogram of the Nigerian resin, are, however, not seen in the chromatograms from the resins of the other three crude oils. The mass spectrum of each resin showed a prominent fragment at *m/e* 191 and a high concentration of the hydrocarbon series C_nH_{2n-8} at C_{27}–C_{31}.

Our preliminary examination of a tetracyclic concentrate (which was also prepared from the thermal diffusion of the urea non-adduct, mentioned earlier) shows that the hydrocarbon series C_nH_{2n-6} in this material lies in the carbon number range C_{26}–C_{31}. The mass spectra show fragmentation patterns which suggest a mixture of steranes incompletely separated from the triterpanes.

Possibly some of the optically active hydrocarbons isolated by Oakwood *et al.*[8], and the hydrocarbon of melting-point 292°–297° C separated from a Colorado shale oil by Cummings and Robinson[11] which has also been referred to by Jones and Dickert[12], are similar in structure to those that we have isolated. Compounds related to picene and hence to pentacyclic triterpenoids have already been isolated from petroleum. Carruthers and Watkin[13] have reported the isolation of 1,2,3,4-tetrahydro-2,2,9-trimethylpicene from an American crude oil, and the triterpene lactone, oxallobetul-2-ene, has been identified in Kuwaiti crude oil by Barton, Overton and Carruthers[14].

Meinschein[6] has identified sterane and terpane hydrocarbon types in sediments and petroleum. The triterpanes that we have isolated may be derived from pentacyclic triterpenoids which are abundantly distributed in the plant kingdom but occur only rarely in the animal kingdom[15]. Animals appear unable to synthesize pentacyclic triterpenoids but build instead the tetracyclic systems derived from lanostane. Our present knowledge of the distribution of the triterpenoids in the plant kingdom[15] is obviously far from complete. It does, however, suggest that pentacyclic triterpenoids are abundantly distributed in terrestrial plants, especially in the more highly specialized phanerograms, whereas they are rare in aquatic plants. Steroids, on the other hand, appear to be abundantly distributed in both aquatic and terrestrial flora. Thus the certain recognition of individual steranes and triterpanes in petroleum may enable the petroleum geochemist to relate this evidence to the flora from which the crude oil most probably originated and recognize a marine or terrestrial origin for each particular crude oil. The evidence reported here indicates that part of Nigerian crude oil may well have had a terrestrial origin.

We thank Prof. D. H. R. Barton, Dr. T. G. Halsall and Dr. G. Eglinton for samples of triterpanes.

POSSIBLE ABIOGENIC ORIGIN OF SOME NATURALLY OCCURRING HYDROCARBONS

By Dr. CYRIL PONNAMPERUMA and KATHERINE PERING

Exobiology Division, Ames Research Center, National Aeronautics and Space Administration, Moffett Field, California

A GROWING body of evidence supports the theory that many compounds of biological significance were formed by the action of various forms of energy on the Earth's early atmosphere before the appearance of life[1–3]. Although such abiogenic processes could have given rise to hydrocarbons, many geologists are inclined to the view that hydrocarbons found in sediments are the result of the degradation of biological material[4]. The possibility of a dual origin, abiogenic and biogenic, has also been suggested[5]. A few hold the extreme view that all hydrocarbons, in deposits ancient or modern, resulted from abiogenic synthesis[6–8].

The analysis of carbonaceous chondrites has revealed the presence of a number of organic compounds which are found in living organisms[9,10]. Similar results have been obtained in the study of Pre-Cambrian sediments[11–13]. Although the question of the origin of these compounds has not been completely solved, the characterization of hydrocarbons present in them has contributed to the understanding of the problem. Results of such enquiries will not only throw light on the path of chemical evolution on earth, but will also lay the guidelines for the analysis of returned lunar samples.

Several criteria have been adopted for the biogenic nature of hydrocarbons whether in ancient sediments or extraterrestrial samples. Considerable importance has been attached to the existence of pristane and phytane[14]. The preponderance of normal hydrocarbons has also been judged to be a factor related to biogenicity[15]. Since hydrocarbons are supposed to be derived from biogenic fatty acids which have an even number of atoms, by the loss of one carbon atom, the excess of odd-numbered hydrocarbons is also regarded as a sign of biological origin[5,16].

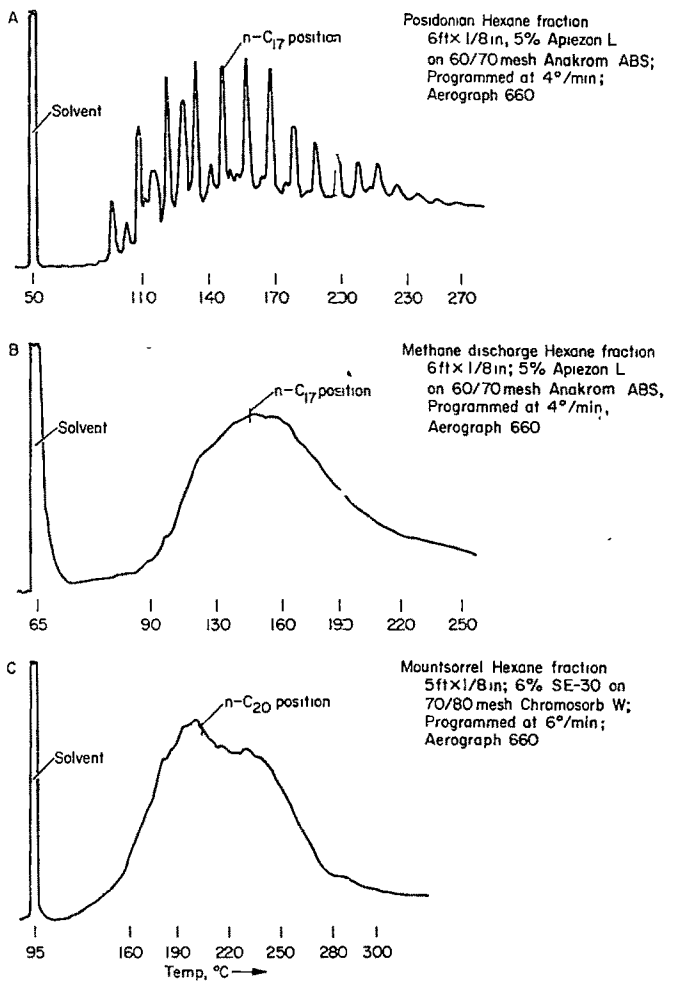

Fig. 1. Gas chromatograms of hexane fractions: (*A*) Posidonian; (*B*) methane discharge; (*C*) Mountsorrel

In order to understand the true significance of such criteria, we decided to compare hydrocarbons synthesized abiogenically with those found in some terrestrial samples. Our previous investigations showed that a variety of hydrocarbons could be synthesized by the action of a spark discharge on methane[17]. The same experiments demonstrated that there is a difference in the nature of the hydrocarbons produced, depending on the type of discharge and the distribution of energies involved. Our earlier analytical studies did not extend beyond hydrocarbons having more than ten carbon atoms.

During the course of this investigation our attention was directed to the existence of hydrocarbons of possible abiogenic origin in the Mountsorrel formation[18,19] near Leicestershire, England. On this site, bitumen occurs in mineral veins. It is found in a tract running from Mountsorrel in Leicestershire to Castleton in Derbyshire, and occurs in a basalt dyke which cuts the granodiorite. The geological evidence put forward by Sylvester-Bradley suggests that these hydrocarbons were deposited during the time that the rocks were formed. The granodiorite itself is Caledonian in age[20]. The possibility that some of these hydrocarbons may have migrated from another source, such as sedimentary rock, should not be discounted. However, according to Sylvester-Bradley, this theory is difficult to support. The oil deposits are found underlying sedimentary rock and, because oil floats on water, it is unlikely that the oil migrated downwards to the igneous rock. Mueller[21] outlined the alternative theory that the mineralizing solutions must have contained hydrogen but not carbon, and that the carbon would have migrated from organic sources in the surrounding sedimentary rock. However, in some places the veins cut through igneous rock which cannot possibly contain carbon. According to Mueller's hypothesis, the carbon must have migrated downwards from overlying sedimentary rocks.

In our present investigations we compared the hydrocarbons from the Mountsorrel formation, claimed to be abiogenic, with hydrocarbons synthesized by the action of a spark discharge through methane, and the hydrocarbons from the Posidonian shale[22], which contain fossils of marine organisms and are generally accepted to be biological in origin. Analysis of the hydrocarbons by gas chromatography and mass spectrometry would highlight similarities and differences among the three samples.

The method used for the synthesis of the hydrocarbons was a slight modification of the one described earlier[17]. The semi-corona head consisted of a 'Pyrex' tube with a 500-ml. flask attached to it. The inside electrode was made of 6-mm-thick stainless-steel tubing extending almost to the bottom of the flask. The narrow head of the flask was covered with a metal foil which served as the outside electrode. The energy sources used were exactly as described before. After a week's discharge through the methane, the deposit on the sides of the flask had the appearance of an oil film.

The Posidonian shale (kindly supplied by Dr. I. A. Breger, U.S. Geological Survey, Washington) was collected from the Bohrung Lingen 330 at a depth of 1,151·0–1,159·5 m. This shale is considered to be Jurassic in age. The specimen analysed did not appear to show any weathering. The exterior of a large piece was carefully washed with water. The sample was then broken and air-dried on a glass plate and the fragments ground in a mortar to 60-mesh size.

Samples of Mountsorrel were collected (under the guidance of Prof. P. C. Sylvester-Bradley) from an area of the Mountsorrel quarry which had been blasted within 48 h of collection. The fresh surface of the rock was further chipped to obtain samples that had not been exposed to the air. The possibility of contamination was thus reduced to a minimum. The samples were canned in air-tight containers and were not opened until the time of analysis. Although the bitumen at Mountsorrel is found in a variety of forms[18]—compact masses, vein-like bodies, globules completely enclosed in dolomite, oily films in calcite geodes, or associated with the dolomite—only the last was used in our analysis as it was judged to be representative of the general composition and was readily ground to a powder of uniform size.

The materials to be analysed were extracted with distilled hexane. Twenty-five grams of the Posidonian and 3 g of the Mountsorrel were each placed in glass soxhlets and extracted for 6 h. In the case of the spark discharge, 100 mg of product were dissolved in hexane. The resulting material, which had a brownish colour in the case of the Mountsorrel and the Posidonian, was evaporated to dryness under a stream of nitrogen. This residue was chromatographed on a 10-cm alumina column. The material on the column was then eluted with 100 ml. of distilled hexane. The aliphatic hydrocarbon fraction which was eluted by the hexane was used for the analysis.

One fraction of the hexane extract was subjected to gas chromatographic analysis on columns of 5 per cent *SE*-30 and 'Apiezon *L*'. A second portion of the

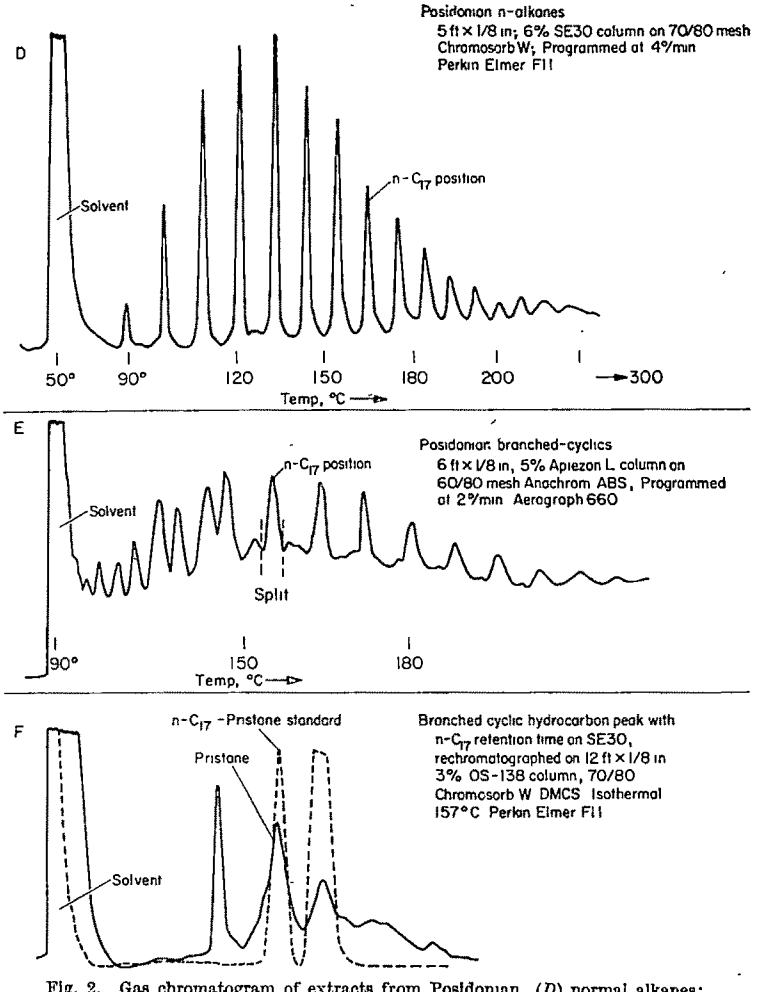

Fig. 2. Gas chromatogram of extracts from Posidonian. (*D*) normal alkanes; (*E*) branched-cyclics; (*F*) pristane fraction

extract was then treated with a 5 Å molecular sieve in order to separate the normal alkanes from the branched-cyclic alkanes. The molecular sieve was activated by heating at 200° C for 2 days in the presence of phosphorus pentoxide in a vacuum. The ratio of sieve to sample was 20 : 1. After sieving for 50 h in dry, distilled benzene, the benzene solution was decanted and the sieve washed with benzene for 1 h. The washings of the sieve were combined with the decanted solution. In order to extract the normal hydrocarbons absorbed by the sieve, it was dissolved in dilute hydrogen fluoride. The normals were recovered by extracting the hydrogen fluoride solution with three times its volume of hexane.

Fig. 1 is a comparative study of the three fractions extracted from the Posidonian (*A*), spark discharge (*B*), and Mountsorrel (*C*). The chromatogram *A* reveals that both normal and branched-cyclic alkanes are found similar to those in hexane extracts of biological shales[12]. The chromatograms *B* and *C*, however, are very clearly unresolved.

The striking feature is the contrast between the chromatograms of the Posidonian and those of the Mountsorrel or the spark discharge. This points out very clearly that the conditions which are sufficient to separate hydrocarbon mixtures obtained from materials which may be described as biological, are not sufficient to resolve the hydrocarbons from either the Mountsorrel or the spark discharge. For *A* and *B*, we used an 'Apiezon *L*' column, but for *C* we used an *SE*-30 column, which could withstand higher temperatures.

Fig. 2 illustrates the effect of molecular sieving on the Posidonian hydrocarbons. The chromatogram of the normal alkanes (*D*) indicates a distribution of normal alkanes ranging from C_{12} to C_{30}. There appears to be no preponderance of the odd numbers over the even. The second chromatogram (*E*) shows the branched fractions obtained after molecular sieving. This illustrates the presence of pristane as determined by its retention time. The pristane fraction was then collected and re-injected on to an *OS*-138·12-ft. column and the result is shown on the third chromatogram (*F*). The identity of the pristane peak is clearly established here by the use of a standard and the superimposition of the standard over the C_{17} peak. Further analysis of the total Posidonian alkane fraction, similar to Fig. 1*A*, on a 100-ft. 0·01 in. 'Apiezon *L*' capillary column, confirmed the presence of both pristane and phytane.

While the use of the molecular sieve very clearly separated the normals in the Posidonian from the branched-cyclic fractions, molecular sieving failed to isolate any such fractions from either the Mountsorrel or the spark discharge. The lack of any detectable amount of normal alkanes in both the Mountsorrel and the spark discharge emphasizes their difference from the Posidonian. A further attempt to resolve the chromatograms of the Mountsorrel and the spark discharge by the use of a 100-ft. capillary column programmed at 2° a minute did not improve the situation. While the large humps shown in Figs. 1*B* and 1*C* spread out to numerous smaller peaks, there were no peaks which stood out significantly. The use of capillary columns emphasized that both the Mountsorrel and the spark discharge material contained a wide variety of hydrocarbons.

Since gas chromatography did not resolve the hydrocarbons in either the Mountsorrel or the spark discharge mixtures, we examined the mass spectra of all three of the extracts. A comparison of fragmentation patterns is illustrated in Fig. 3. An overall comparison of the three mass spectra once again shows very clearly that both the Mountsorrel and the spark discharge hydrocarbons are different in nature from the Posidonian hydrocarbons.

The fragmentation patterns obtained from the Posidonian exhibit rather high intensities at *m/e* of 141, 155, 169, and 183 (*G*). These fragments have been associated with isoprenoid mass spectra[23]. On the other hand, the fragmentation patterns of the Mountsorrel (*I*) and the spark discharge (*H*) show only very minor intensities at these ion masses. In fact, the distribution of peaks occurring in these spectra is scarcely indicative of the presence of any significant amount of saturated normal and isoalkanes, The spectra point to the presence of highly unsaturated compounds of a highly ordered nature. Preliminary evidence from bromination appears to confirm a high degree of unsaturation in both the Mountsorrel and spark discharge hydrocarbons.

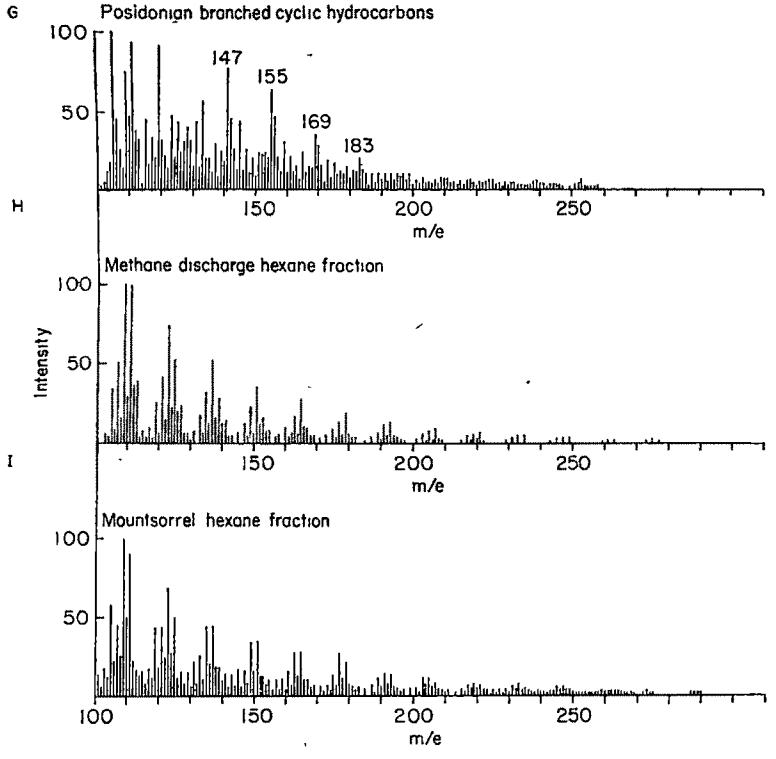

Fig. 3. Mass spectra of, (*G*) Posidonian branched cyclic hydrocarbons; (*H*) methane discharge hexane fraction, (*I*) Mountsorrel hexane fraction

Elemental analysis of the Mountsorrel formation showed that there was scarcely any nitrogen present in the compound, and there was no evidence of porphyrins[24]. A preliminary analysis for fatty acids by gas chromatography and thin-layer chromatography produced negative results. Infrared spectra also pointed to the absence of any carbonyl function. The presence of porphyrins, of fatty acids, and some carbonyl function is generally associated with biological oils.

The evidence presented from the gas chromatographic and mass spectrometric analysis shows very clearly that the hydrocarbons from the Posidonian shale, which is recognized to be associated with marine sediments, are strikingly different from those in both the Mountsorrel and the spark discharge material. The chemical evidence for the biological nature of the Posidonian revolves around the presence of (*a*) porphyrins[22,25]; (*b*) normal alkanes; (*c*) saturated branched chain isoprenoid-type compounds, especially pristane and phytane.

The hydrocarbons produced by the spark discharge on methane are truly abiogenic. They show no normals or saturated branched chain isoprenoids. The Mountsorrel

extract does not exemplify any of the characteristics associated with biogenicity illustrated by the Posidonian, but shows a marked similarity with the hydrocarbons synthesized by the spark discharge. On the basis of the chemical evidence presented, one is led to infer that the hydrocarbons in the Mountsorrel formation were produced by a process very different to that which produced the hydrocarbons in the Posidonian and are possibly abiogenic in origin.

We thank Dr. I. A. Breger for samples of the Mountsorrel and Posidonian; Prof. P. C. Sylvester-Bradley and Mr. R. J. King for valuable discussions and help in collecting samples from the quarry in Mountsorrel; Dr. A. L. Burlingame for use of his mass spectrometer; Dr. B. Nagy for help with the thin-layer chromatography analysis of the extracts for fatty acids; and Mr. F. Woeller for providing the hydrocarbons synthesized by the semi-corona discharge.

EUROPEAN MID-DEVONIAN CORRELATIONS

By Dr. PAUL COPPER
Department of Geology, Imperial College of Science and Technology, London, S.W.7

In recent palaeontological literature, much attention is being devoted to the structurally complex group of atrypoid brachiopods, many species of which locally serve as valuable index fossils. Taxonomic revision on a generic level has not kept pace with the rapidly increasing number of new species, and a number of new genera need be proposed. The introduction of the atrypoid genera *Mimatrypa* Struve 1964 (ref. 1), *Spinatrypina* Rzhonsnitskaya 1964 (ref. 2), and *Pentlandella* Boucot 1964 (ref. 3) has filled part of the gap. Another genus, restricted in distribution largely to one type of sediment and fauna, is added in this article.

The new genus *Atryparia* (Latin suffix *arius, a, um*, pertaining to) is closely related to and probably derived from the genus *Atrypa* Dalman 1828. It belongs to the subfamily Atrypidinae, family Atrypidae under the classification at present accepted. The new genus contains a number of new species generally obscured under the name *Atrypa globosa* Leidhold 1928 (ref. 4) (non *Atrypa reticularis* var. *globosa* Barrois 1889—ref. 5) in Eifelian stratigraphy. *Atrypa globosa* Leidhold is shown elsewhere[6] to be synonymous with *Mimatrypa desquamata* (Sowerby 1840). *Atryparia* n.gen. is easily separated in all stages of ontogeny from associated specimens of *Atrypa* Dalman, although it is rarely as abundant.

Atryparia n.gen.

Type species: Atryparia instita n.gen., n.sp. *Range:* Nohn beds to Ahbach beds, Eifelian, Middle Devonian (Fig. 1). *Distribution:* Germany, Belgium, France, Algeria, Morocco.

Diagnosis: Large, generally widely frilled, biconvex atrypids with coarse, strongly divergent, shallow and undulating ribs. Frills hug the shell wall and do not cause the interruption of ribs into 'rows' as in *Spinatrypa* Stainbrook 1951. Growth lines as in *Atrypa*. Beaks are appressed in all ontogenetic stages, and no interarea or delthyrium is exposed. The ventral umbo is expanded and rather angular. The foramen is often enlarged into the apex.

Internally, a pedicle layer or collar is characteristic, but deltidial plates are absent. A distinctive, clear-cut dental nucleus (equivalent to an embryonic lateral cavity) marks the tooth. Dorsal cardinalia tend to massivity and are thickly reinforced. The minute notothyrial pit holds a weak cardinal process, overlapping the hinge plates. Crura are straight, unfeathered. Disjunct, two-layered jugal processes contain nodules and terminate in long, sub-vertical, straight jugal plates. Spiralia with about fifteen whorls. Musculature similar to *Atrypa*.

Comparison: The genus is distinguished from *Atrypa* by its coarser, shallower, diverging ribs, strong ventral apical globosity, continually appressed beak and complete absence of deltidial plates. Internally, it is marked by its massive dorsal cardinalia, large and well-developed jugal plates and dental nuclei. In Devonian *Atrypa* the absence of dental nuclei is notable.

Atryparia n.gen. could be confused with some *Spinatrypa* which have poorly developed or broken spines, but it is still distinguished by the absence of rib rows and delthyria.

Remarks: The genus particularly favoured a substrate of clayey calcareous shale or thinly bedded argillaceous limestone showing an absence of detrital debris. Locally it is associated with horn corals and the most common accompanying atrypid is *Spinatrypa*. It only rarely outnumbers all other fauna. Frills are common on many specimens, even where the associated *Atrypa* show no development at all.

Flamand[7] illustrated a specimen, possibly related to *Atryparia*, from the Devonian near the Algeria–Morocco border in north Africa. Quenstedt[8] would seem to have been the first to figure species of the genus, calling them *Terebratula prisca* Schlotheim 1820. Collections from France and Belgium show the genus to be represented there. Its main distribution is probably limited to Western Europe and North Africa. In the Eifel region of Germany, at least three, possibly five, species, each with a

restricted vertical distribution, can be identified. A brief diagnosis of two member species follows. Details are to be published in a major paper. Descriptions are based on a small collection of about 800 specimens.

Atryparia instita n.gen., n.sp.

Derivatio nominis: instita (Latin) = a seam, border or flounce. Characteristically the species has a marked frill.

Holotypus: Specimen in Fig. 2, 1–4. *Locus typicus:* north-east flank of Mühlenberg, 800 m north-east of Niederehe, Hillesheim syncline, Eifel. *MTB Dollendorf* r5455 : h7473. *Stratum typicum:* upper layers of Müllert horizon, Ahbach beds, upper Eifelian (Fig. 1).

Associated fauna: Spinatrypa kelusiana Struve, rare *Atrypa* sp.

Diagnosis: Globose *Atryparia* with well-developed, thick, ventrally turned frills, equally convex valves except in late maturity. Ribs markedly flattened. Umbonal areas strongly convex (although not as angular as in middle Eifelian species). Internally, a cemented, elevated pedicle collar is typical.

Atryparia stabilia n.gen., n.sp.

Derivatio nominis: stabilia (Latin) = things that are stable. The ventral valve is planar, giving the shell a stable position.

Holotypus: Specimen in Fig. 2, 5–8. *Locus typicus:* Weinberg quarry, 1 km north-west of Kerpen, Hillesheim syncline, Eifel. *MTB Dollendorf* r5098 : h7572. *Stratum typicum:* Bohnert sub-horizon, Nollenbach horizon, Freilingen beds, upper Eifelian (Fig. 1). Common down

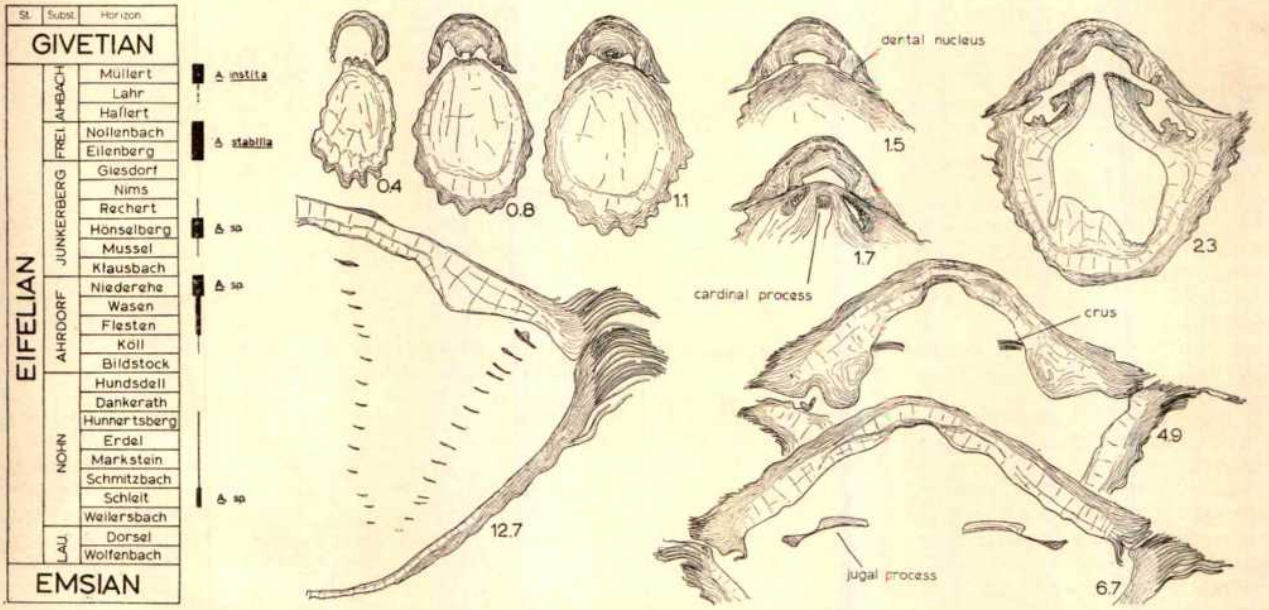

Fig. 1. Left: Stratigraphic column of the Elfel area, Germany, showing chronological distribution of *Atryparia* n.gen. Right: Transverse serial sections of *Atryparia institia* n.sp., paratype *Pc*354.*C*279*i*, Müllert horizon. Intervals in mm (× 2·5). (Abbreviations: *A.* = *Atryparia*, Lau. = Lauch, Frei. = Freilingen.)

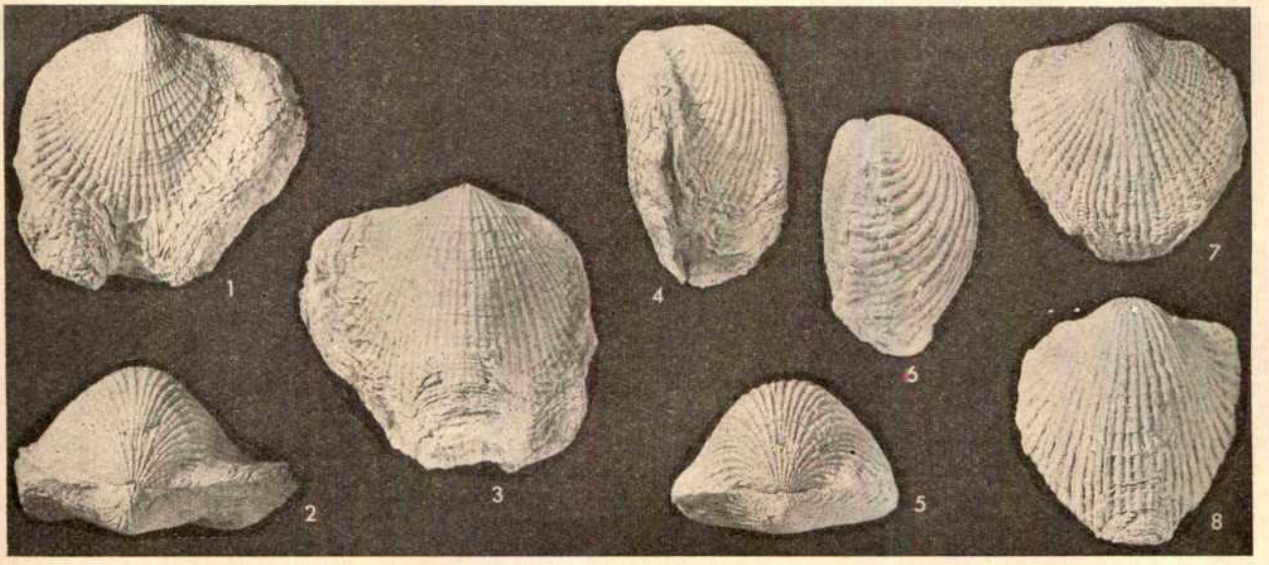

Fig. 2. 1–4, HOLOTYPUS *Atryparia institia* n.gen., n.sp., *Pc*351.*C*279*i*, Müllert horizon, *MTB Dollendorf* r5548: h7739 (× 1). 5–8, HOLOTYPUS *Atryparia stabilia* n.gen., n.sp., *Pc*355.*C*345, Nollenbach horizon, *MTB Dollendorf* r5093: h7572 (× 1)

to Eilenberg horizon, Freilingen beds. *Associated fauna: Kerpina vineta* Struve, *Carinatina plana* (Kayser), *Spinatrypa aspera* (Schlotheim), *Atrypa* aff. *squamifera* (Schnur).

Diagnosis: Flattened ventral and strongly convex dorsal valves show more prominently etched, deeply troughed ribs than *Atryparia instita* n.sp. Frills generally lacking; valves much flatter in early ontogenetic stages. Beak blunted, hinge margins straightish. Internally, a pedicle collar is lacking and the dental nuclei are very clearly defined.

Species of the new genus promise to be of considerable value in Mid-Devonian correlations of Europe, and have successfully been used in the Eifel for detailed biostratigraphy. Straight-line trends are still not fully known, although ribs appear to become progressively coarser, and there is a size increase in younger forms. It is likely also that there was little or no development of a pedicle layer in lower Eifelian species and that this structure became progressively more complex.

NORTH MEDITERRANEAN CLIMATE DURING THE LAST WÜRM GLACIATION

By ENRICO BONATTI

Institute of Marine Science, University of Miami, Miami, Florida

IT is generally assumed that non-glaciated regions at temperate latitudes were subjected to cool and humid climate (pluvial) during Pleistocene glacial maxima[1]. Data obtained recently in south European areas bordering with the Mediterranean seem, on the contrary, to give evidence of markedly arid climate during the last Würmian Glacial, as also pointed out by Van der Hammen *et al.*[2].

The data in question include the following:

(*a*) Pollen sequences from the sediments of Monterosi and Baccano[3], two crateric lakes of central Italy (Fig. 1) lying at an altitude of about 200 m above present sea-level. Their combined pollen diagram has been dated using carbon-14 at ten levels, and shown to extend continuously from about 25,000 years ago to the present. From 25,000 to about 15,000 yr. B.P. (that is, during the second maximum of the Würmian glaciation) the area in question was essentially treeless, and was covered by a cold steppe, with *Artemisia* as the dominant plant (Fig. 2). This steppe gave way to a grassland from about 15,000 to 12,000 yr. B.P., then to a shrubland (with *Corylus*), which preceded forestation at about 11,000 yr. B.P., that is, in correspondence with the 'Alleröd' of northern Europe. During most of the Post-Glacial period a forest (with *Quercus* dominant) was prevalent in the region. This sequence suggests cold-arid climate during the Glacial period, gradually giving way to warmer and humid conditions in the Post-Glacial.

(*b*) The presence of a Würmian steppe according to the Monterosi sediments is confirmed by a cold steppe fauna, with *Elephas primigenius*, *Equus idruntinus* and *Capra ibex*, which is recorded as having inhabited central Italy during the last Würmian peak[4].

(*c*) Pollen diagrams from lacustrine deposits at Fimon and Arqua in the eastern Po River Valley, a few metres above present sea-level[5], show an early phase where there is a paucity of arboreal vegetation and a dominance of *Artemisia*, which suggests an arid steppe environment. No carbon-14 datings have been published for these sequences, but Lona[5] attributed this portion of the diagrams to the last Glacial peak. In both diagrams *Corylus* precedes the establishment of an oak-dominated forest in the Post-Glacial, as in the Monterosi sequence.

(*d*) Preliminary pollen spectra and three carbon-14 datings of a thick peat deposit from Macedonia, Greece, have been published recently[6]. Again a steppe environment with *Artemisia* dominant prevails during the last Glacial, while a humid oak forest takes over in the Post-Glacial. Older portions of the diagram suggest that similar alternations have been present also in previous Pleistocene glacials.

(*e*) Pollen diagrams from Spain[6] reveal sequences very similar to that shown in Fig. 2. For example, carbon-14 datings have been made of a diagram from the Lagoon of Sanguijuelas in north-western Spain at seven levels; this goes from about 15,000 yr. B.P. to the present. The full Glacial is thus not represented in it; even so, during the earliest 3,000 yr. of this sequence (that is, during the Tardiglacial) the non-arboreal pollens are prevalent, and dominant among them are steppic general such as *Artemisia* and *Ephedra*, while in the Post-Glacial a forest with 'Quercetum' becomes prevalent. Other diagrams from coastal areas of southern Spain have many features in common with the diagrams from central Italy, but do not extend farther back in time than the Post-Glacial.

Fig. 1. Some of the locations where evidence of Würmian arid climate was obtained: (*a*) Monterosi and Baccano lakes; (*b*) Lazio region with cold steppe fauna in the last Glacial; (*c*) Lakes of Fimon and Arqua; (*d*) Deposit of Tenagi Philippon, Macedonia; (*e*) Lagoon of Sanguijuelas

Present results thus suggest that the main features shown in Fig. 2 are to be considered valid for the whole north Mediterranean, supporting the concept of a prevalently arid climate in this area during the last Würmian peak.

A tentative explanation for the diminished precipitation in the north Mediterranean contemporary with glaciations at higher latitudes would be as follows: much of the precipitation in the south

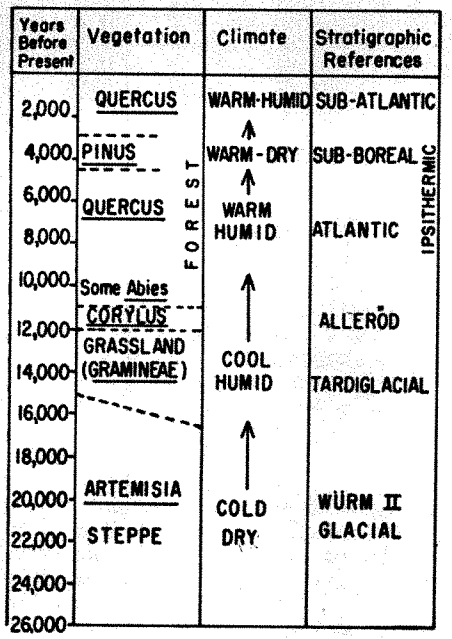

Fig. 2. Generalized scheme of the vegetation and climatic changes in central Italy at moderate altitudes from the last Glacial maximum to the present. Data derived from pollen analyses of sediment cores from Monterosi and Baccano. The time scale is based on ten carbon-14 measurement datings of the cores. The main features of this diagram appear to be generally valid for south European regions

European regions derives at present from westerly cyclonic air masses which originate over the Atlantic, where they pick up most of their moisture. During Glacial maxima the temperature of the surface water of the north Atlantic at intermediate latitudes on the average was approximately eight degrees lower than at present[7]. As a result evaporation was also lower, and drier cool winds would sweep southern European regions. At the same time, according to Emiliani and Geiss's scheme[8] of the glaciations, relatively warm water was transported into the north-east Atlantic and adjacent seas by the Gulf Stream. Such water masses would provide the moisture to feed north European ice sheets advancing southwards from the Scandinavian areas.

In addition to being drier, the aforementioned westerly air masses were probably less frequent in the Mediterranean during glacial maxima, being repelled by cold, dry winds entering the Mediterranean from the north-east (Russia). Such winds were presumably more intense and frequent than at present, due to a greater temperature gradient between glaciated north-east European areas and North Africa during glacial maxima. The increase in temperature of Atlantic water at the end of the Glacial together with the diminished importance of the north-easterly winds would cause increasing precipitations in southern Europe, and development of a humid climate, as indicated by the Post-Glacial portion of the aforementioned pollen profiles.

Evidence of aridity in southern Europe during Glacials should be detectable in Mediterranean deep-sea sediments. Indeed, cores from the western Mediterranean show Würmian sections where wind-borne minerals (mainly quartz) are prevalent; such eolian components disappear in the Post-Glacial[9]. It is also to be expected that sedimentation rates in the north Mediterranean should be highest during Late-Glacial phases due to stronger erosion on adjacent land, related to the melting of the Würmian glaciers and to the paucity of vegetation.

I thank C. Emiliani and A. Stefanon for their advice. This work was supported by the U.S. National Science Foundation and the Office of Naval Research.

BINDING OF CATIONIC DYES TO NUCLEIC ACIDS AND OTHER BIOLOGICAL POLYANIONS

By Dr. J. E. SCOTT and Dr. IRENE H. WILLETT
Medical Research Council Rheumatism Research Unit, Canadian Red Cross Memorial Hospital, Maidenhead, Berkshire

THE precipitation of polyanions by cationic dyes in its simplest form can be expressed:

$$P^{z-}zM^{+} + zR^{+} \rightleftharpoons P^{z-}zR^{+} + zM^{+}$$

where P^{z-} is a polymer P with z anionic sites, M^{+} the counterion and R^{+} the precipitating cation. Applying the law of mass action to this equation in a 'model' treatment neglecting activity coefficients, it can be shown that the ratio of the concentrations $[P^{z-}zR^{+}]/P^{z-}zM^{+}]$ changes from very low to very high values inside a narrow range of the ratio $[R^{+}]/[M^{+}]$ if z is large (for example, > 10). If the concentration $[R^{+}]$ is constant, the position of the sharp inflexion in the curve of $[P^{z-}zR^{+}]/P^{z-}zM^{+}]$ against $[R^{+}]/[M^{+}]$ can be expressed in terms of $[M^{+}]$. The region of $[M^{+}]$ in which the ratio $[P^{z-}zR^{+}]/[P^{z-}zM^{+}]$ changes markedly is defined as the 'critical electrolyte concentration' (CEC) (refs. 1, 2). The equilibrium constant determines the value of the critical electrolyte concentration, and is in turn governed by the relative affinities of R^{+} and M^{+} for the polyanionic sites[2].

'Affinity' is the sum of all the forces acting between the participants. Coulombic and van der Waals forces, hydrogen bonds and charge transfer may all be involved. An examination of a large number of polyanions, electrolytes and precipitants has shown that in those cases in which Coulombic interactions predominate, there is a distinctive pattern of critical electrolyte concentrations, and therefore of relative affinities of M^{+} and R^{+} for the polyanion[3]. The critical electrolyte concentration depends primarily on the type of anionic site on the polymer. Critical electrolyte concentrations are grouped in the order CEC ($-COO^{-}$) < CEC ($=PO_4^{-}$) < CEC ($-SO_4^{-}$) when R^{+} is an ion of low electrostatic field and polarizing power, and in the opposite sequence when R^{+} contains a chelated Al^{+++} or similar cation with a high polarizing power[4].

Molecular weight and charge density are factors affecting the critical electrolyte concentration, but except when they are low they are less important than the charge type[5].

In those cases in which the charge is not due to chelated Al^{+++}, etc., the structure of R^{+} around the cationic site can be considerably changed without altering the critical electrolyte concentration pattern[3]. The charge may be centred on one, or spread over several atoms, which may

include nitrogen, carbon or sulphur, or the cation may be polyvalent. Substituents which 'shield' the cationic charge from the anionic site lower the critical electrolyte concentration.

The establishment of a pattern of Coulombic behaviour permits the interpretation of variations from this pattern in terms of extra contributions from van der Waals forces, hydrogen bonds, etc. Thus, we find that the behaviour of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) towards a range of dyes differs from that of polyphosphates in general. This appears to be a consequence of interactions between the dyes and the purines and pyrimidines of the polynucleotides.

The critical electrolyte concentration phenomenon has been used to localize tissue polyanions with greater specificity than is possible using the dye (alcian blue) alone[2,6]. This article describes an extension of that work, using a wider range of dyes and polyanions.

The dyes used in this investigation were standard histological preparations from B.D.H. Ltd., Poole, Dorset; G. T. Gurr, Ltd., London, S.W.6; or (in the case of alcian blue and alcian yellow) gifts from Imperial Chemical Industries, Ltd., Blackley, Manchester, through the courtesy of Mrs. S. M. Neal. Polyanions, other than polynucleotides, were prepared by the method of Scott[7], and were gifts from Dr. F. E. T. Pautard and H. Zola (onuphic acid[8]), Dr. S. Gardell (keratansulphate), Dr. Cifonelli (heparan sulphate, chondroitin sulphates *A* and *B*) or were commercial samples (heparin, alginate, polyacrylate, polyphosphate). Some polynucleotides were commercial samples (thymus DNA, from Worthington Biochemical Corp., New Jersey, U.S.A.; polyadenylic and polyuridylic acid from Miles Laboratories Ltd., Elkhart, Indiana, U.S.A.; RNA core from Koch-Light Laboratories, Colnbrook, Buckinghamshire), but for the most part were made by the method of Kirby[9,10].

Polyanion solutions were spotted and dried on circles of Whatman No. 1 filter paper, which were then immersed in solutions containing dye and salt. The dyes were at 0·01 per cent w/v. All except those containing aluminium chloride were in 0·05 M sodium acetate buffer *p*H 5·7. After a minimum of 1 h at room temperature the papers were blotted and dried in air. The critical electrolyte concentration of a particular polyanion–dye complex was taken to be the highest concentration of electrolyte at which staining of the polyanion 'spot' was apparent. Binding to carbohydrate polyanions of thioflavine *T*, 9-amino acridine, acridine orange and pyronine was conveniently and sensitively assessed in ultra-violet light (Shandon 'Chromatolite'). Unbound dye fluoresced brilliantly, whereas bound dye did not. Similar observations on polynucleotides were not so easy to interpret, owing to the presence of ultra-violet absorbent material in the polyanion, and in these cases results were recorded in daylight. The results are shown in Table 1. Although similar and even more striking results were obtained in solutions of magnesium chloride, results in Table 1 are quoted in sodium chloride, since many polynucleotides are precipitable by Mg^{++}, thus rendering interpretation more equivocal.

Within the group of polyanions containing $-COO^-$ and/or $-SO_4^-$ groups and no aromatic rings, CEC ($-COO^-$) < CEC ($COO^- + SO_4^-$) < CEC ($-SO_4^-$). This sequence is the same as that observed for a large number of organic cations[3]. In general, critical electrolyte concentrations are low, and in some cases staining was observed only in the absence of added sodium chloride, that is in the presence of 0·05 M sodium acetate buffer. In the case of methyl green the buffer electrolyte was sufficient to prevent staining of most of this group of polyanions.

Critical electrolyte concentrations of those polyanions which possess aromatic rings, as purines or pyrimidines, are much higher. The difference is particularly striking in the case of pyronine. Other dyes behave similarly to those shown in Table 1, for example, methylene blue, thionine, toluidine blue, safranin, crystal violet and 'Rivanol'. In view of the wide range of chemical structures involved, the most reasonable explanation of the enhanced binding lies in extra interactions due to conjunction of aromatic systems of dyes and polyanions.

More sites should be available for interaction on single-stranded molecules with less secondary structure than on those with much double-stranded or other secondary structure. RNAs in general have higher critical electrolyte concentrations than DNAs. The lower critical electrolyte concentration of thymus DNA, as compared with rat liver DNA, is probably attributable to its greater secondary structure, due to dissimilar preparative procedures, or to native differences in the structure in the chromosomes. Up to 80 per cent of DNA of the interphase lymphocytes is in the repressed chromatin fraction[11] and DNA from the repressed chromatin has a higher T_m[12] than that from active chromatin[13], indicating a greater degree of secondary structure. Using a spectrophotometric method, Drummond *et al.*[16] have shown that there are more binding sites available to amino-acridines on thermally denatured DNA than on native DNA. Ribosomal RNA (ref. 10) which had been converted into the tetraethyl-ammonium salt, dissolved in 50 per cent ethanol and then recovered as the Na^+ salt (RNA rat liver I) showed a higher critical electrolyte concentration than ribosomal RNA which had been isolated as the Na^+

† Staining was not present in 0·0 M sodium chloride.

salt without the step involving solution in 50 per cent ethanol as the tetraethyl-ammonium salt (RNA rat liver II). Since this step was associated with some loss of secondary structure, the higher critical electrolyte concentration may indicate stronger dye binding due to interaction with purines and pyrimidines thus exposed. (This is especially clear in the case of alcian blue.)

Polyadenylic acid, with purine rings, offers greater potential interaction than polyuridylic acid with the smaller pyrimidines, and shows a much greater critical electrolyte concentration.

Experiments were carried out in aqueous solutions containing potassium, magnesium or lithium acetates, with 9-amino acridine or 'Rivanol'. The results were in substantial agreement with those shown in Table 1, and will be reported in detail elsewhere.

Two dyes stand out from the pattern. Methyl green is a poor precipitant for polyanions in general. DNA, however, shows a very marked and specific interaction, which is not suppressed by salt. Heat-denatured DNA shows much less affinity, implying that the double-stranded helix is necessary for this interaction. It is possible that intercalation between base pairs occurs, with alignment of the two cationic charges of the dye with ionized phosphate ester groups at opposite sides of the helix. The roughly complementary critical electrolyte concentration pattern of pyronin and methyl green is of interest histologically, and this aspect will be discussed elsewhere.

Alcian blue behaves as though it were bound only by electrostatic forces. It appears to be a better precipitant of carbohydrate polyanions than the other dyes, and its interaction is not very sensitive to suppression by electrolyte. In one instance only, with rat liver RNA (I), does the generalization not hold, and in this case the evidence shows that the RNA structure is abnormally open, with good sites available for extra binding. It seems that alcian blue can bind with forces additional to electrostatic bonds, but that it does not normally do so. In this respect it differs from all other cationic dyes tested. The geometry of the molecule is unlike that of other dyes[3]; the cationic charge is not part of the chromophore, it is polyvalent, and it is very bulky. Any one factor could upset the alignment of ring systems and charges necessary for two modes of binding. Alcian yellow, another cationic dye based on the copper phthalocyanine ring, behaves similarly to alcian blue.

Table 2. CRITICAL ELECTROLYTE CONCENTRATIONS (IN MOLARITY ALUMINIUM CHLORIDE) OF DYE–POLYANION COMPLEXES ADSORBED ON FILTER PAPER

† Staining was not present in 0·0 M added aluminium chloride.

Similar evidence for two modes of binding was obtained by experiments with dyes which depend for their cationic charge on chelated Al^{+++} (Table 2). The pattern of critical electrolyte concentrations is CEC $(-SO_4^-)$ < CEC $(-COO^- + SO_4^-)$ < CEC $(-COO^-)$ and CEC $(-SO_4^-)$ < CEC $(=PO_4^-)$. This pattern is identical with that of 'affinities' of small highly charged inorganic cations for $-COO^-$, $=PO_4^-$ and $-SO_4^-$ (ref. 14). It seems that the character of the electrostatic interaction of mucicarmine, aluminon, and haematoxylin is determined by that of the chelated ion. The presence of purines and pyrimidines in the polyanion considerably increases the critical electrolyte concentrations, as in the non-chelate dyes, and is presumably due to similar causes, namely interactions between aromatic systems of dye and polyanion. The histological implications of this pattern in the chelate dyes will be discussed elsewhere.

The role of purines and pyrimidines in the binding of dye-like molecules to polynucleotides has been controversial since it was first suggested[15]. Measurements of metachromasia[16], fluorescent yield[17], thermal denaturation[18] and chemical reactivity of intrahelical amino groups[19] have all pointed to the existence of more than one type of binding. Intercalation provides for an extra mode of binding, apart from purely electrostatic combination with $=PO_4^-$, but a 'stacked' dye array would also provide additional affinity[20] without the necessity for intercalation. Calculations of free energies of intercalation and 'stacked dye' models[16] showed that, although both had less than DNA itself, the intercalated model had least. It is possible that intercalation and stacking can co-exist. Fluorescent quenching and metachromasia have been shown to vary according to the base composition of the polynucleotides[17,21]. Although it is difficult to interpret such findings in a way that does not involve interaction between dye and purine or pyrimidine base, the lack of a firm diagnostic method for electrostatic binding, inclusive of random and stacked arrays, in the presence of non-electrostatic binding, is conducive to confusion. The present semi-quantitative method permits an assessment of the contribution of the $=PO_4^-$ by relating it to $-COO^-$ and $-SO_4^-$ (by analogy, the properties of bromine could be related to those of chlorine and iodine). In this method a phase transition is involved, which restricts comparisons with other data, most of which have been obtained in aqueous solution. The results strongly suggest that there is an extra interaction with polynucleotide bases, which is modified by the occurrence of secondary structure in the polynucleotide, in qualitative agreement with the experimental data previously cited[16,21]. The type of interaction is not definable, but probably involves at least van der Waals and 'hydrophobic' bonds.

If it is true that some disruption of secondary structure enhances binding of aromatic compounds, it implies that small aromatic molecules may exert their maximum biological effect while secondary structure is being built up or broken down, that is, during replication and transcription.

We thank Dr. K. S. Kirby for generous gifts of RNAs and DNAs and for very useful discussion of the manuscript. Mr. Terence Stacey gave valuable assistance.

TRANSFORMATION OF FIBROUS TISSUE TO BONE *IN VIVO*

By Prof. C. ANDREW L. BASSETT* and Dr. THOMAS P. RUEDI†
Orthopaedic Research Laboratories, Columbia University College of Physicians and Surgeons, New York, New York

NUMEROUS investigations and debates have been concerned with the source of osteogenic cells during the past century. In recent years, investigations carried out with tissue culture techniques[1,2] and with the aid of tritiated thymidine[3,4] or electron microscopy[5] have indicated that mesenchymal cells, particularly those associated with vessels as perivascular connective tissue cells, may specially act as osteoblasts. The term 'osteoprogenitor' has been applied to these cells[4]. For several years, work in these[2,6] and other laboratories[7] has indicated that it is the environment in which the cell resides that determines largely whether it will produce or destroy bone, cartilage or fibrous tissue. In view of these observations it may be presumptive to label a particular cell as an osteoprogenitor cell until it has responded to its micro-environment and begun forming bone—at which time it is an osteoblast. Generally it is agreed that the osteoblast synthesizes collagen, mucopolysaccharides and, probably, lipids[1]. These organic fractions of the extracellular osseous matrix are later mineralized in a pattern which is characteristic, at the ultrastructural level. Calcium hydroxyapatite crystals are arranged in and on the collagen fibrils, with their *c*-axes parallel to the long axes of the fibrils[8,9]. This pattern has been mimicked by collagen in tendon exposed to tissue fluids *in vitro*[10] and by turkey tendon being converted to bone[11], suggesting that pre-existing collagen can be altered so that it is mineralized.

This article reports the pattern of healing of 'Millipore'-isolated defects in the cortex of canine radii, in which additional features of the behaviour of osteogenic cells and the transformation of fibrous tissue to bone were observed. The operative technique, described previously[12], produces a chamber measuring 0·4 × 2 cm (Fig. 1) which is open to cells entering from its proximal or distal cortical ends and not directly from the marrow cavity, periosteum or overlying soft tissues. In the present investigation, groups of 3–5 adult animals were killed 8, 12, 16, 21, 24, 27, 30, 60, 180 and 320 days after operation and multiple serial histological sections were prepared from the regions of the defect. Initially the chambers were filled with a fibrin clot which was invaded by vessels and spindle-cells in a centripetal manner. This invasion occurred at different rates in different animals, depending largely on the number of cells migrating into the chamber by way of Haversian and Volkmann canals in the cortex at the ends of the chambers. After 21–31 days, most chambers were filled with a dense fibrous connective tissue (Fig. 2). This fibrous tissue seemed to be transformed directly to fibre bone and, eventually, to mature lamellar bone so that, after 320 days, cross-sections through the middle of the defects were indistinguishable from the unoperated cortex proximally and distally (Fig. 3). Newly forming bone was always anchored to pre-existing bone. No cartilage was observed in any of these 'Millipore'-ensheathed specimens. At the interface between the new bone and fibrous tissue, collagen bundles were continuous (Fig. 4). In the regions where they emerged from the woven fibre bone, these fibre bundles frequently were surrounded by plump, secretory, polygonal cells with basophilic cytoplasm and a clearly defined Golgi apparatus. These cells seemed to develop from spindle cells already present between the collagen fibres. The front of newly formed bone advanced steadily toward the centre of the chambers in a centripetal fashion, until all fibrous tissue had been converted into bone. In some animals the process was completed in 60 days, while in others small amounts of residual fibrous tissue were found in the centres of the chambers after 180 days. Although conversion of fibrous tissue began as early as 16 days, lamellar bone appeared primarily after the defects were bridged by fibre bone. At no time were significant numbers of multinucleated osteoclasts observed in the bone formed in the defects. The dead cortical bone at the ends and sides of the defects, however, was replaced ('revitalized') by the alternative waves of osteoclasis and osteogenesis, characteristic of creeping substitution.

These experimental studies suggest that mature fibrous tissue may be transformed directly to bone. The process has certain histological features in common with those reported by Johnson[13] during the ossification of turkey tendon and during the moving of teeth by orthodontic forces[14]. In the case of this and the turkey tendon study, spindle cells, apparently dormant between the bundles of

collagen fibres, became plump, secretory and resulted in the conversion of a non-mineralized connective tissue to a mineralized connective tissue. Whether these spindle cells should be referred to as osteoprogenitor cells or mesenchymal cells seems more a problem of semantics than practicality. The major point is that they altered their functional state at specific times and in specific locations. While the exact nature of the cellular activity involved in this mineralization process is not evident from this study, two possible explanations seem to exist. First, the cells may have produced materials which, when added to the collagen already present, rendered the collagen 'calcifiable'. Protein–polysaccharide complexes and/or lipids have been thought by others[13,15] to be involved in such a mechanism. On the other hand, it is possible that cellular activity may have removed agents inhibitory to calcification, such as pyrophosphate[16].

In the chambers of some animals the osteogenic response was so explosive that bridging by fibre bone was almost complete in 30 days, while in others it advanced very slowly and required 6 months to fill the gap with bone. These differences appeared to be related mainly to the rate at which cells could enter the chamber during the first 2 weeks after operation. Afterwards, the differences seemed to correlate with the rate of cell proliferation and, possibly, the amount of instability of the radius resulting from the procedure and the activity of the animals. The chronicity of the osteogenic response in some animals suggests that the stimulus for continuing bone formation may be different from that of an acute injury potential. The findings of this investigation are consistent with the view that osteogenesis requires a large number of cells with the proper genetic endowment, a nutritional environment that will support them, and a stimulus, the nature of which is still unidentified. They should encourage orthopaedic surgeons faced with treatment of fibrous union or pseudarthrosis, for they demonstrate that mesenchymal cells, residing in fibrous tissue, probably retain a capacity to form bone when properly stimulated.

Osteoblastic activity was noted where prominent, longitudinally oriented, collagen bundles emerged from bone. Frequently, these bundles seemed to be arranged along lines of tensile stress and linked the two ends and sides of the defect. Similar behaviour, that is, osteoblastic activity, is observed on the tension side of a tooth being moved by orthodontic forces[14]. Bone formation occurs between the fibres of the periodontal membrane where they emerge from alveolar bone. Furthermore, bone formation in tendon has been reported when tensile forces are excessive[17]. Although it is not known exactly how mechanical factors can stimulate this type of cell specialization, recent investigations have demonstrated that bone[18–20] and tendon[21] have piezoelectric properties and generate an electric signal in response to deformation. Furthermore, weak currents, artificially induced in bone, have been observed to affect osteogenesis[22], and it is likely that currents of similar magnitude, generated *in vivo*, may control the metabolic activity of osseous cells[23].

Finally, while the conversion of non-mineralized connective tissue to mineralized connective tissue was associated with characteristic cell activity, the conversion of fibre bone to lamellar was not. There were remarkably few multinucleated osteoclasts or resorption cavities during the reparative process. Furthermore, lamellar bone began to appear in the defect only after bridging by fibre bone was virtually complete. Is it possible that the stress patterns in the bridged chambers focused local electro-mechanical stimuli on osteocytes, thereby stimulating them to carry out cyclic, internal remodelling of the immature, weak bony structure? Such a cycle of osteolysis and osteogenesis by osteoclastic and osteoblastic osteocytes has been indicated by the recent studies of Bélanger[24].

This work was supported by the U.S. Public Health Service through the National Institutes of Health.

ORIGIN AND NATURE OF THE CUTICULA DENTIS

By Prof. J. J. HODSON
Department of Oral Pathology, University of Sheffield

THE dental cuticle first described by Gottlieb[1,2] is one of the most controversial structures in dental histology and pathology. Gottlieb described it as a 'horn layer' or 'membrane' frequently formed by the outer enamel epithelium covering the tooth crown (secondary enamel cuticle), and later, by proliferation, the root cementum. Around this structure Gottlieb[1–6] built up theories which are still largely accepted to-day concerning the eruption of the teeth, surface protection against caries, the pathology of periodontal disease, the gingival sulcus and the attachment of the gum to the tooth surface and their importance in the health and disease of the periodontium.

In histological sections stained with Ehrlich's haematoxylin and eosin Gottlieb's cuticle appears as an eosinophilic or unstained, clear, hyaline or granular membrane-like layer of varying thickness (2–15μ), lying between epithelium and the tooth surface (Fig. 2*A* and *C*), or applied to the tooth surface after loss of the epithelium. In unstained sections it appears refractile and bluish-green.

Its presence, form and general appearance are well documented[7–23]. Nothing is known of the origin of the dental cuticle and little regarding its chemical nature. Although it is almost universally accepted as being a keratinous structure, Sicher[21,24] and others have recently revived Weski's[7] and Lehner's[16] conclusions that it is not keratin formed by maturation of epithelial cells but a 'keratoid' cementing substance secreted by epithelial cells. Schüle[25,26] carried out extensive histochemical and physical investigations but gave insufficient evidence of his identification of the secondary cuticle. Wertheimer and Fullmer[22] found that the cuticle protein was not a keratin but contained a prosthetic carbohydrate of unusual composition. They interpreted their results, however, as strongly indicating an epithelial origin[27]. Almost all authors believe the dental cuticle is derived from epithelium. Turner[20] believed that it was a modification of the acquired salivary cuticle, while Waerhaug[28] suggested it could be merely a thickening of the primary cuticle.

More than 1,000 surgical and autopsy specimens of human permanent and deciduous teeth have been examined with and without their periodontium; some animal jaws were also examined, including the dog, hamster, rat and rabbit. Gottlieb's cuticle was observed irregularly distributed in 75 per cent of the teeth of the permanent dentition and considerably less in the deciduous dentition (estimated at 10 per cent). The dental cuticle was observed in some animals[30].

The cuticle was found on the exposed surfaces of the teeth but more commonly between the gingival epithelial cuff and the enamel and cementum. The cuticle on the cementum was identical in all respects with that on the enamel. It was also found in three of twelve unerupted teeth examined. In many cases in parts of its course it was composed of up to five or six layers often separated by remnants of degenerate epithelial cells or linear markings giving a laminated appearance (Fig. 1*C*). In some specimens the cuticle was present between cells of the epithelial cuff and not between the epithelium and the tooth surface. Present also were bulbous, circular and other shapes either at the termination of the cuticle or along its path which projected into the epithelium (Fig. 1*C*, 2*A*) or, not infrequently, appeared as separate 'bodies'. Investigations[30] have shown that the cuticle, 'hyaline bodies' and the multi-layered strips (noted also by Gottlieb[2] and Turner[20]) were identical with the 'hyaline bodies' present in some odontogenic cysts and elsewhere[9,27,29,31]. The similarity of the latter to the cuticle had been previously noted[9,31], but the paradontal 'hyaline bodies' have not been previously described[30].

It was clear from these and other observations that the cuticle did not arise either as a product of or a maturation

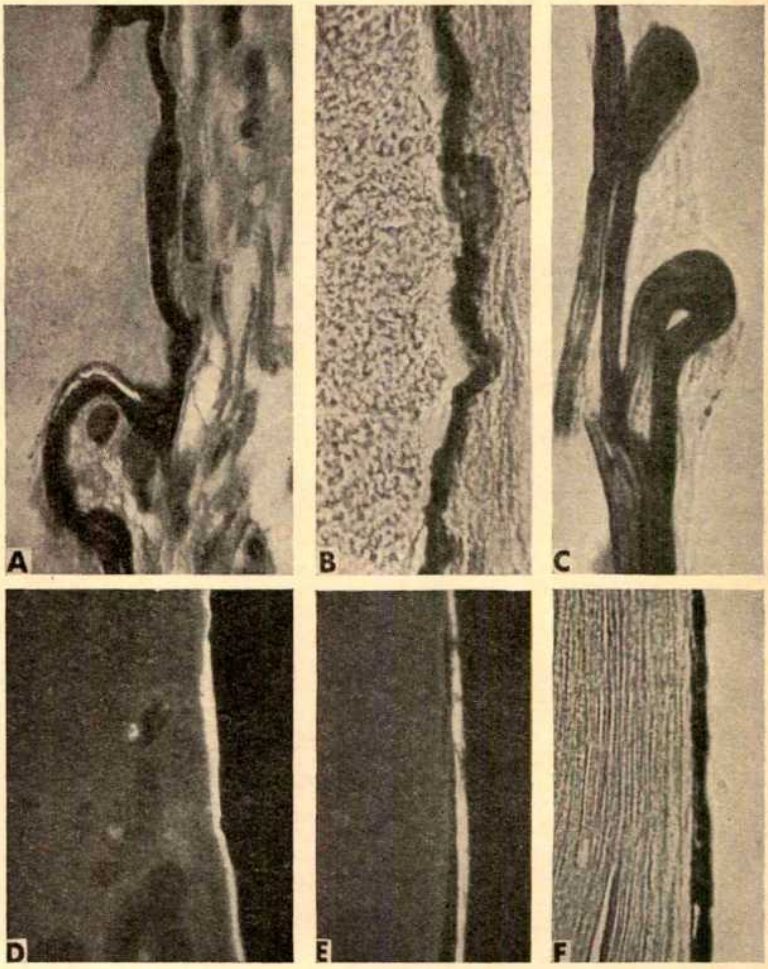

Fig. 1. *A*, 'Cuticle' between non-vital bone and squamous epithelium; stained orcein only (24 h) (× 770). *B*, 'Cuticle' between epithelium (right) and calculus mass; stained T.P.A. method, no counterstain (× 770). *C*, Multi-layered, laminated 'cuticle' with 'hyaline bodies' within and between epithelium (right) and cementum; stained Gomori's chromic acid methenamine (× 770). *D*, Autofluorescence of natural 'cuticle' on mandibular incisor between epithelium (left) and enamel surface (365 mμ) (× 770). *E*, Autofluorescence of experimental 'cuticle' of globin on an epithelial surface (left) (× 770). *F*, From same experiment as *E* showing globin layer stained by the T.P.A. method (× 770)

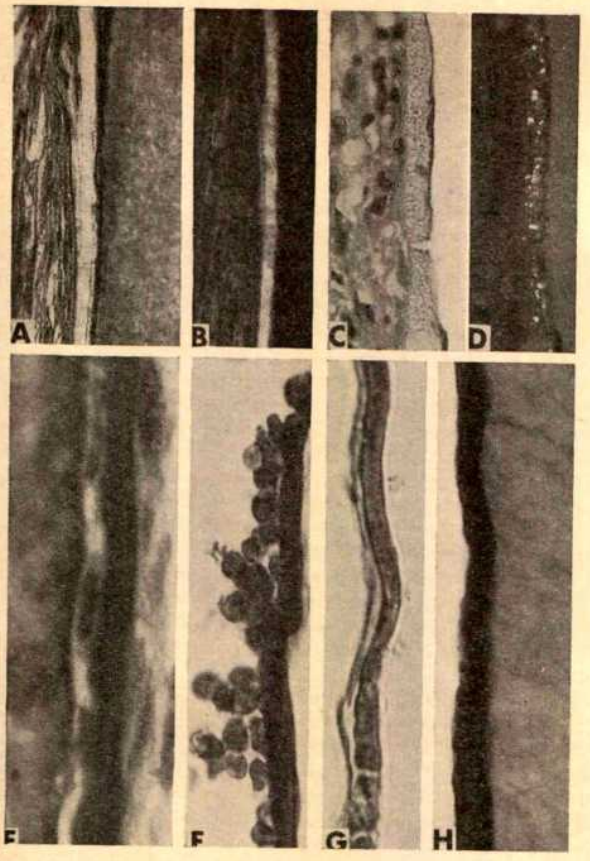

Fig. 2. *A*, Clear 'cuticle' between epithelium and cementum. Note bulbous projection and epithelial remnants between upper layer and cementum; haematoxylin and eosin (× 770). *B*, Same as *A* photographed by polarized light. *C*, Granular 'cuticle' between epithelium and enamel surface; haematoxylin and eosin (× 770). *D*, Same as *C* showing birefringent particles. *E*, Showing transitional stage of 'cuticle' from deep eosinophilia (on right, adjacent epithelial cells) to a clear layer with residual eosinophilic material (on cementum surface); haematoxylin and eosin (× 1,230). *F*, A stage of formation of experimental 'cuticle' showing conglutination of erythrocytes against wax (dissolved) to simulate enamel. Shows forming haemoglobin layer (right) and adjacent unpressed corpuscles; haematoxylin and eosin (× 770). *G*, Similar to *F*, but more complete layer. Note single erythrocytes still visible in lower part; haematoxylin and eosin (× 770). *H*, Similar experiment but, in place of wax, erythrocytes pressed and conglutinated against the surface of dentine to simulate cemental 'cuticle'. Compare with right side of layer in *E* (× 770)

of surface epithelial cells, or that it was a special structure of the enamel epithelium or paradontal epithelial cuff. This was further supported by the occurrence of similar hyaline layers in positions other than the classical sites[30], as for example on the enamel in dentigerous cysts, between hyperplastic epithelium and the cementum surface between tooth roots, between hyperplastic epithelium and the pulpal dentine within the pulp canal, between non-vital bone and encircling epithelium (Fig. 1*A*), between layers within calculus masses and between calculus and adjacent epithelium (Fig. 1*B*), between gingival surface epithelium and supra-gingival calculus deposits, and also, among other places, between cholesterol crystals where no epithelium was present. The layer was also found between epithelium and root apices in granulomatous lesions or in the process of exfoliation. Three such cases, including the case first observed by Gottlieb, appear in the literature[2,10,32].

A series of observations were made which led to a new approach to the problem of the origin and nature of the cuticle and enabled experiments to be devised to reproduce the membrane-like layer *in vitro*[30]. From the large amount of material examined, a consistent picture of the early stages of its formation was obtained. The structure appeared as a deeply eosinophilic layer of material with a slight basophilia, granular or homogeneous in consistency, varying greatly in thickness and density and developing first into a pale red, then yellowish and finally a poorly stained or unstained clear, glass-like or sometimes granular layer (Fig. 2*A* and *C*). All stages of transition from one appearance to the other were observed. Sometimes the red stage gradually or suddenly passed into the yellow and then the clear stage; in other cases the yellow or clear stage contained varying amounts of residual eosinophilic material or granules (Fig. 2*E*), which gradually diminished and disappeared as the layer became entirely clear.

Concurrently with these findings, other investigations highlighted a remarkable similarity in haematoxylin- and eosin-stained sections, between layers of keratin and membrane-like layers composed of conglutinated erythrocytes. These layers showed a number of structural features similar to those found in the cuticle. In various stages of change the cuticle showed structures which appeared to be fragmented erythrocytes.

There are no specific histochemical reactions for denatured haemoglobin, and its demonstration in tissues is difficult. Most of the general histological stains used stained the cuticle and erythrocytes in a similar manner. In some of the deeply eosinophilic cuticles an unequivocal positive reaction was obtained with the peroxidase method of Pickworth[33] for identification of haemoglobin. Reactions for iron were mostly negative. The most significant result was that obtained using the tannic acid–phosphomolybdic acid–amidoblack method for haemoglobin (which stains a deep blue) described by Puchtler and Sweat[34] and later revised by Puchtler, Rosenthal and Sweat[35] (T.P.A. method). In connexion with my studies on tissue haemorrhage, a thorough investigation of the T.P.A. method had been carried out using a wide variety of normal and pathological material, as well as various chemical and other preparations of haemoglobin and globin. The specificity of the reaction was most precise (Fig. 3), and my work supports the suggestion[34] that this stain affects the protein part of the haemoglobin molecule and reflects structural chemistry rather than amino-acid composition. The T.P.A. method showed a remarkable selectivity for the dental cuticle even at 2–3μ thick, staining it a deep blue (Figs. 1*B* and 3). The positive results with the peroxidase reaction, the specificity with the T.P.A. method, the appearances with general histological stains, and the morphological evidence in the early stages of formation showed that the dental cuticle was a haemoglobin product. It was also found that cuticle layers

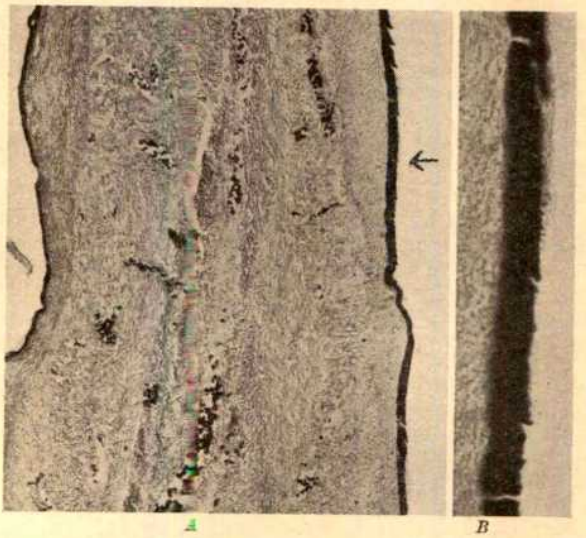

Fig. 3. *A*, Coronal section through interdental tissues of human mandibular incisors showing the newly described 'paradontal hyaline layers' between the reduced enamel epithelium and the enamel surface—note their close application to the epithelium, the specificity of the colour reaction and the similar precise staining of single erythrocytes and those in vessels (× 90). *B*, Area arrowed in *A* under higher magnification. Stained T.P.A. method, no counterstain (× 770)

exposed to the oral environment assumed a yellow or brown colour and lost their affinity for the amidoblack and many other stains. The nature of the residual eosinophilic material in the clear layers previously mentioned was investigated by staining with methyl-violet and comparing their appearances with natural and artificially produced Heinz bodies[36,37]. Their similarity suggested that they could be similar denaturation products of haemoglobin.

The elastic tissue stains were also found to be highly selective for the dental cuticle, hyaline layers and bodies except in the earliest stages of formation. Fullmer and Wertheimer[38] were the first to demonstrate the selective action of orcein on the cuticle (Fig. 1*A*), but they did not investigate other elastic tissue stains. My material showed an equally consistent selective reaction using Weigert's resorcin-fuchsin stain, Verhoeff's stain and Fullmer and Lillie's orcinol-new fuchsin[39]. With Gomori's[40] aldehyde fuschin stain for elastic tissue a positive (but variable) reaction was obtained. Using elastic tissue stains in conjunction with eosin, it was possible to trace in some specimens a transition from an unreactive part of the cuticle to a highly selective reaction. It appeared that after the layer had formed, a physical and probably a chemical change occurred in the denatured globin which apparently produced properties simulating some of those shown by elastic tissue. It is interesting to note that elastic fibres stain a pale blue with the T.P.A. method.

When examined by ultra-violet light (356 mμ) the cuticle in the light eosinophilic, yellow, or clear stages showed an intense bluish white autofluorescence (Fig. 1*D*), which was weaker or absent in the deeper eosinophilic stages. As tryptophan was found to be present it was probable that this was responsible for most of the fluorescence. The eosinophilic areas apparently contained substances, probably haem, in a state which caused a transfer of electronic energy, accounting for the reduction or quenching of the fluorescence[41]. In detail there were variations in the intensity of fluorescence which probably reflected variations in the complex nature of the degradation products of the haemoglobin[42,43]. Hileman[44] observed only a weak autofluorescence in the cuticle probably due to the examination of cuticles in the eosinophilic stages. When examined by polarized light, the layer showed a variable birefringence in a manner similar to the autofluorescence, the yellow or clear areas showing stronger birefringence than the less changed layers (Fig. 2*B*). It may be noted here that elastic tissue shows autofluorescence but not birefringence. In some of the clear cuticles highly birefringent particles were observed (Fig. 2*C* and *D*). These were possibly crystalline degradation products of haemoglobin rather than included foreign material as suggested by Turner[20].

The histochemical reactions obtained indicated the presence of sulphydryl groups, tryptophan, reducing substances, and some non-glycogen carbohydrate. Critical evaluation of many tests for lipid strongly suggested its general absence, but some residual lipid was present in a few cases; the blue sudan-black reaction was not due to lipid. What happened to the phospholipid of the erythrocyte stroma was not clear. The histochemical reactions showed variable results which might be expected in view of the chemical complexity of the denatured haemoglobin and the insensitivity of the methods available. However, the results obtained, together with the reactions of the selective and general stains, the structural features and the known properties and behaviour of squamous epithelium, indicated that a derivation from epithelium was a biological impossibility. The general and selective staining reactions and some of the histochemical reactions showed that the substance was not keratin, and no other substance with the properties described could arise from epithelial cells. The epithelial cells often showed no orientation in relation to the substance. The proximity to epithelium has in the past misled investigators into believing that it must be derived therefrom, whereas with a few exceptions, including the 'hyaline bodies', the cuticle is a structure lying between epithelium and the tooth surface. Rather than suggesting attachment of the cuff epithelium to the tooth surface, it indicates that there is a space which can be occupied by material foreign to the part.

As the cuticle was found to be composed essentially of erythrocytes deposited and conglutinated outside the normal influence of metabolic and catabolic changes associated with the vascular and reticulo-endothelial system (that is, between epithelium and the tooth surface or between epithelial cells), experiments were devised to reproduce it *in vitro* by pressing packed erythrocytes and various preparations of haemoglobin and globin[45] against hard surfaces (Fig. 2*F–H*), or between epithelial surfaces (Fig. 1*E* and *F*). Using these and other methods, membrane-like layers were produced with morphological and staining characters closely simulating those of the dental cuticle in both sectional and spread preparations. Layers as thin as 1–2μ were produced, thus explaining the very thin, amidoblack positive cuticles which could be mistaken for the so-called 'primary cuticle'. The thickness of one red cell in sections is likely to be less than 3μ. The fluorescent and birefringent properties of the experimental layers also paralleled those of the cuticle. Up to the present it has not been possible to reproduce the stage which reacts with the elastic tissue stains. Observations of membrane-like layers of keratin, parakeratin, fibrin and serum were also made, but these showed no close resemblance to the cuticle.

Summarizing, these investigations show that the dental cuticle is a fortuitous formation, foreign to the part, of haematogenous origin and composed of denatured haemoglobin. Since Gottlieb's 'hornified membrane' is neither a cuticle nor a membrane, and is, strictly speaking, a pathologically formed layer, it is suggested that it be re-named the 'haematogenous paradontal hyaline layer'. The role hitherto accorded to the 'dental cuticle' in the structure, physiology and pathology of the teeth and periodontium will, in the light of the new findings, need reconsideration. It is somewhat paradoxical that the structure considered for so long to bind the gingiva to the tooth surface should itself indicate that no such union exists.

I thank Mr. M. L. Lehman for work on the translation of the original papers by Gottlieb and other German literature. I also thank Prof. C. Lendrum for advice, Dr. B. Stevens for discussions on fluorescence and Mr. M. Rudland and Mr. A. Murdoch for technical assistance. This work was supported in part by a grant from the Research Fund of the University of Sheffield and in part by the Medical Research Council.

SYNTHESIS OF A RIBONUCLEIC ACID VIRUS BY THE MAMMALIAN OVUM

By RALPH B. L. GWATKIN and SUSAN AUERBACH

King Ranch Laboratory of Reproductive Physiology, Department of Animal Biology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia

THE experiments described in this article are part of a research programme which has two basic aims. One is to explore the potential value of viruses as experimental tools in the study of early mammalian development. The other is to determine in greater detail the known relationship of viruses to birth defects.

The ultimate intention is to work with temperate viruses; nevertheless, initial experiments were made with a virulent virus so that any effect on egg development could be readily detected. The agent selected was Mengovirus, a picornavirus consisting of spherical particles 27–28 mμ in diameter[1]. Previously it was reported[2] that addition of the 37*A* heat-stable strain[3] of Mengovirus to cultures of two-cell mouse eggs prevented further development of the ova and ultimately caused their necrosis. These effects were clearly due to Mengovirus, since purified virus preparations were active at high dilution and were blocked by anti-viral serum. Interestingly, the zona pellucida, which was expected from other data[4] to exclude macromolecules, proved quite permeable to this virus.

Once Mengovirus was found to produce an ovo-pathological effect, the next phase of the investigation was to determine whether the egg was capable of supporting the synthesis of new virus particles. This article shows that virus synthesis does occur. However, the one-step growth curve is different from that in either mouse fibroblasts or *L* cells.

The methods used for obtaining and culturing two-cell ova have already been described[2]. The culture medium used for maintaining them *in vitro* was developed by Dr. R. L. Brinster[5]. Its essential components are sodium pyruvate (which replaces the sodium lactate used in a previous formulation) and crystalline bovine plasma albumin in a bicarbonate-buffered balanced salt solution. Zonae pellucidae were removed with 0·25 per cent pronase in phosphate-buffered saline, containing 1 per cent polyvinylpyrrolidone. This enzyme was also used to prepare the monolayers of mouse embryo cells used in the plaque assays[6].

To establish conclusively whether mouse ova could synthesize Mengovirus, the virus was diluted in culture medium to about 10,000 plaque-forming units (P.F.U.) per ml. and a series of 0·01 ml. drops were placed under mineral oil in plastic Petri dishes. Half the series of drops served as controls, while the remainder each received ten zona-free ova. The cultures were then incubated in 5 per cent carbon dioxide. After 24 and 48 h, each drop was transferred to 1 ml. of culture medium. These samples were then frozen and thawed three times to release any intra-ovular virus present. The virus content of each sample in terms of plaque-forming units was determined by plaque titration on monolayers of mouse embryo cells.

After 24 h incubation the virus content of the drops containing eggs was somewhat lower than the controls, indicating adsorption of virus to the ova. However, after 48 h half the drops with eggs were found to contain relatively large numbers of virus particles (Fig. 1), proving conclusively that the two-cell mouse ovum is capable of supporting the synthesis of this RNA virus. The inefficiency of adsorption due to the low virus concentration could have been one reason for our failure to demonstrate virus synthesis after 24-h incubation. However, another reason turned up when the one-step growth curve of Mengovirus in two-cell ova was determined in the next series of experiments.

Ova, free of their zonae pellucidae, were placed in a concentrated suspension of Mengovirus (10^9 P.F.U./ml.) for 60 min at 37° C. This treatment had previously been shown to bring about infection of all the eggs present. Unadsorbed virus was then removed by transferring the ova serially through five 0·5-ml. amounts of culture medium contained in the depressions of a glass spot-test plate. Three separate micropipettes were used during this

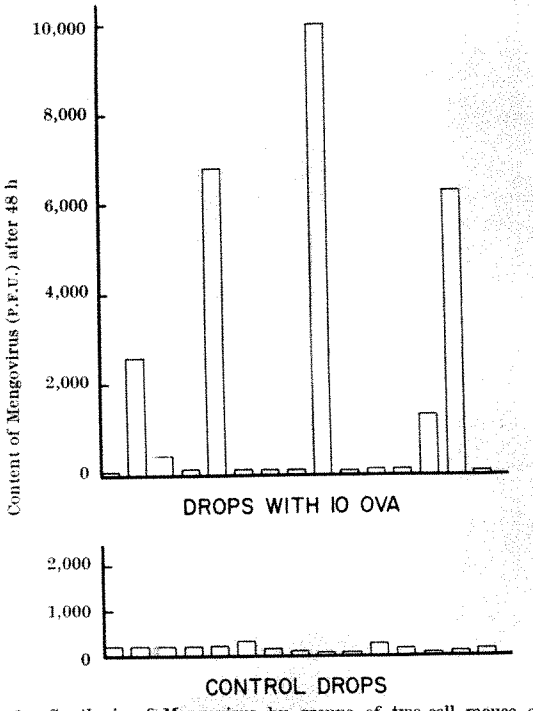

Fig. 1. Synthesis of Mengovirus by groups of two-cell mouse ova added to drops containing small numbers of virus particles. Assays were made 48 h after adding ova

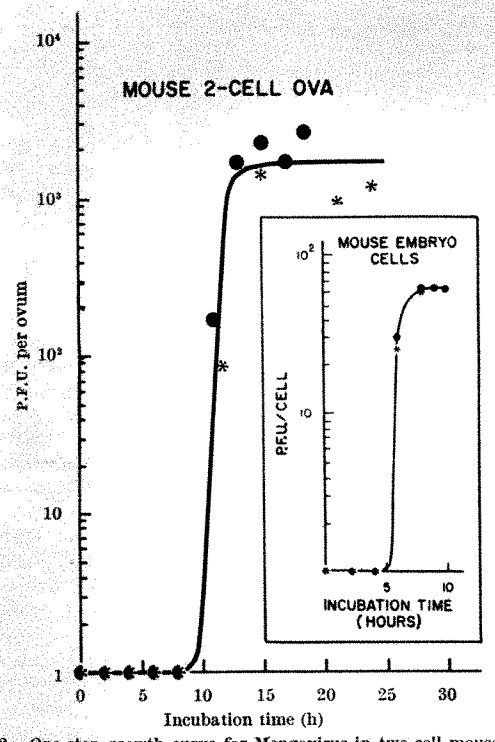

Fig. 2. One-step growth curve for Mengovirus in two-cell mouse ova. The inset shows the curve obtained with mouse embryo cells (predominantly fibroblasts)

washing process to minimize carry-over of virus. The washed ova were finally placed in a series of 0·01-ml. drops of medium under mineral oil; ten ova per drop. Culture dishes were incubated at 37° C under 5 per cent carbon dioxide and at intervals triplicate drops were sampled and titrated as in the previous experiment. For the first 8 h of incubation (Fig. 2) no virus was detected, but by 11 h about 100 P.F.U. were formed per egg. A maximum titre of about 1,700 P.F.U. per egg was reached by 13 h. At about this time necrosis was observed in some of the ova.

For comparison, a growth curve was constructed using primary mouse embryo cells, collected after one *in vitro* passage when they appeared to be predominantly fibroblasts. Because of the relatively small size of these cells compared with the ova the procedure for obtaining the growth curve was modified slightly. Sufficient virus to infect all the cells was added to a monolayer and the culture was incubated for 60 min at 37° C. The cells were then removed with pronase and washed repeatedly by low-speed centrifugation to remove unadsorbed virus. Groups of fifty cells were placed in microdrops and then processed exactly as the eggs had been. The inset in Fig. 2 shows the growth curve obtained. The latent period was about half that in the eggs. Virus synthesis in the fibroblasts was complete in about 8 h, whereas in the eggs it had not yet commenced at this time.

The mean number of infectious virus particles produced by each fibroblast was approximately 65. Brownstein and Graham[3] have reported a one-step curve for the 37*A* strain of Mengovirus in mass suspension cultures of *L* cells. Their curve displays the same characteristics as we obtained from the fibroblasts, with the exception of a greater yield (500 P.F.U. per *L* cell). If allowance is made for the larger size of the *L* cell (a mean volume of 905μ^3 compared with 140μ^3 for the average mouse fibroblast—see ref. 7), then the virus produced per unit volume is nearly the same for both cell types (0·5 P.F.U./μ^3). However, the two-cell ovum (approximate volume, 344,000μ^3—see ref. 7) yielded about 1,700 P.F.U. per ovum, or 0·005 P.F.U./μ^3. This is only 1 per cent of the virus produced by the somatic cells on a unit volume basis.

The reason for the relatively slow and inefficient viral synthesis by the ovum when compared with other cells is not known, but it may be due to an immaturity of the subcellular particles, particularly the ribosomes, involved in building the new virus units. Experiments are being planned to test this working hypothesis.

We thank Mr. Dorsey Williams for his assistance. This work was supported by a grant from the National Science Foundation. One of us (R. G.) is in receipt of a career development award from the U.S. Public Health Service.

PENICILLINASE-NEGATIVE VARIANTS OF METHICILLIN-RESISTANT *Staphylococcus aureus*

By Dr. STEPHEN J. SELIGMAN
Department of Medicine, University of California Centre for the Health Sciences, Los Angeles

THE contribution of penicillinase activity to the methicillin resistance of methicillin-resistant staphylococci has been controversial. Penicillinase can inactivate methicillin, although the V_{max} and the relative affinity of substrate for enzyme are only 1/30th and 1/12000th respectively of the values for benzylpenicillin[1]. Cultures of methicillin-resistant staphylococci may inactivate more methicillin than do cultures of methicillin-sensitive staphylococci[2,3]. But under comparable conditions of growth and induction, both types destroy similar amounts of the antibiotic[4,5]. The rate of such destruction is relatively low and 8–24 h is usually needed in order to reduce appreciably the concentration. Sutherland and Rolinson examined methicillin-resistant strains isolated from diverse sources and found that these strains consisted of a majority population with a comparatively slight increase in methicillin resistance and a minority population with a considerable increase in methicillin resistance[6]. In our laboratory we have confirmed that the minority population consists predominantly of mutants with increased intrinsic resistance. If penicillinase production were not a significant factor in methicillin resistance, then penicillinase-negative variants should have a degree of resistance comparable with their penicillinase-positive parents. Eriksen and Erichsen, however, reported that such variants of one strain were significantly less resistant to methicillin and concluded that resistance to methicillin was due both to penicillinase activity and to inherent resistance[7]. This article reports an experiment which I undertook to isolate and evaluate penicillinase-negative variants from five methicillin-resistant strains.

The penicillinase-negative variants were detected by Novick's test in which penicillinase-positive colonies take on a purplish colour resulting from the precipitation of an acid-insoluble *p*H indicator, *N*-phenyl-1-naphthylamine-azo-carboxy-benzene, when the colonies are exposed

to penicillin[8,9]. Loss of penicillinase activity was confirmed by a modified Got's test[10]. Evaluation of methicillin resistance was carried out by a method similar to that used by Sutherland and Rolinson[6]. Dilutions of a broth culture were pipetted on to a series of plates containing increasing amounts of methicillin up to 500 μg/ml. Three of the strains were from the same sources as those investigated by Sutherland and Rolinson. Two of these had populations with resistance patterns similar to their report, but one had a majority population with an increase in resistance to 125 μg/ml. This was strain No. 8054 which Stewart and Holt had previously reported to be of uniformly high resistance to methicillin[11]; however, even this strain contained a small population of more highly resistant mutants. Two additional methicillin-resistant strains were supplied by Prof. William M. M. Kirby. These American isolates had a composition of methicillin resistance similar to the European strains as described by Sutherland and Rolinson[6]. All five methicillin-resistant strains contained spontaneously occurring penicillinase-negative variants in a frequency of about 10^{-3} (Table 1). The penicillinase-negative variants produced a small number of highly resistant cells with the ability to form colonies on 500 μg/ml. methicillin plates. The number of such colonies, their growth rate, and their eventual size were comparable with those observed with their penicillinase-positive parents. Comparison of results on lower concentrations of methicillin indicates that the penicillinase-positive variants produced relatively more colonies on plates from 2·5 to 5 μg/ml. methicillin (Table 2). The lack of proportionality between colony count and size of inoculum found at 5 μg with the penicillinase-positive strain and at 2·5 μg with the penicillinase-negative variant is similar to that which was occasionally observed with ampicillin and *E. coli*[12]. The ability of relatively more colonies to grow with more dilute inocula is contrary to what would be predicted from an inoculum effect due to penicillinase. In some experiments the penicillinase-positive variants gave rise to comparatively more colonies than their penicillinase-negative descendants up to 50 μg/ml. with diluted inocula and up to 250 μg/ml. with undiluted inocula. If one assumes that the loss of penicillinase activity was not accompanied by the loss of any other genetic characteristics which contribute to methicillin resistance, then the ability of more penicillinase-producing colonies to grow on the lower concentrations of methicillin is at least partially a result of penicillinase activity. At 500 μg, however, growth is entirely associated with increased intrinsic resistance. With either penicillinase-positive or penicillinase-negative strains, growth in broth cultures containing 5 μg/ml. resulted in the selection of a population, many of the cells of which could grow as isolated colonies up to at least 500 μg/ml. Accordingly, the contribution of penicillinase activity to methicillin resistance is variable, depending on the test used to measure resistance. The resistance of the small number of highly resistant mutants is independent of penicillinase activity. Since the rate of inactivation of methicillin by penicillinase is low, significant inactivation would not be expected in clinical situations in which the supply of methicillin is frequently replenished, and it would appear that exposure of such methicillin-resistant strains to comparatively small concentrations of methicillin can result in the selection of highly resistant variants. The highly resistant mutants, however, grow more slowly than their parents[12a]. Consequently, their pathogenicity may also be lowered.

Genetic control of penicillinase activity appears to be associated with an extra-chromosomal element or plasmid[8]. Methicillin-resistant clinical isolates have almost invariably been penicillinase producers, although a few penicillinase-negative strains have been reported[13]. Acridine dyes have been found to cause a modest increase in the frequency of penicillinase-negative variants in some strains[14,15]. Other workers have not encountered an increased frequency[9]. With the present strains an increased frequency of penicillinase-negative variants was not demonstrated after exposure to the highest two-fold dilution of acriflavine which gave turbid growth overnight in trypticase soy broth at *p*H 7·3 (usually 12·5 μg) or *p*H 7·6 (usually 3·13 μg). Resistance to mercury salts[16] was found by Richmond and John to be co-eliminated and co-transduced with penicillinase formation[17]. They concluded that the genetic

determinants of these traits were closely linked on the same plasmid. In the current strains, resistance to mercury salts was lost at the same time as penicillinase was lost in all cases (Table 1).

Tetracycline resistance was reported in one staphylococcal strain to be associated with a plasmid[18]. Of fifteen penicillinase-negative isolates from six separate experiments with strain No. 5982, only one variant had lost its resistance to tetracycline, and it would seem that tetracycline resistance in No. 5982 is not on the penicillinase plasmid. Sutherland and Rolinson[6] and Stewart and Holt[11] have reported that No. 8054 was tetracycline-resistant, but the strain supplied to us through the courtesy of Drs. B. M. Kagan and E. R. Martin was sensitive to 3 μg/ml. tetracycline—a finding which indicates loss of tetracycline resistance after serial passage in several laboratories and consistent with loss of a plasmid.

In conclusion: (1) Penicillinase-negative variants of methicillin-resistant *Staphylococcus aureus* maintain the capacity to produce mutants highly resistant to methicillin. (2) American isolates of methicillin-resistant staphylococci were similar to European strains. (3) Loss of penicillinase activity occurred spontaneously and was not increased by acriflavine. (4) Tetracycline resistance was not on the penicillinase plasmid.

ELECTROPHORETIC AND FUNCTIONAL HETEROGENEITY OF PEPSINOGEN IN SEVERAL SPECIES

By Dr. W. B. HANLEY* and SAMUEL H. BOYER

Division of Medical Genetics, Department of Medicine, The Johns Hopkins University and Hospital, Baltimore, Maryland

AND

M. A. NAUGHTON

Department of Biophysics, The Johns Hopkins University School of Medicine, Baltimore, Maryland

FOR many years now, claims have been made for the existence of more than one acid-activated gastric proteolytic enzyme. Until recently such evidence depended on differences in *p*H optima, substrate specificities, and degrees of activation or inactivation by different agents. This evidence has been thoroughly reviewed and appraised by Taylor[1].

Recently a number of investigators have utilized column chromatography to isolate several pepsins from gastric juice and pepsinogens from gastric mucosa. For example, Ryle and Porter[2] separated, from crude porcine pepsin, pepsin itself and two minor components which they named parapepsin I and II. Investigation of the physico-chemical and enzymatic properties leaves little doubt, despite similarities, that these enzymes have separate identities. Chromatographic fractionation of crude pepsinogen from porcine gastric mucosa enabled Ryle[3] to isolate the zymogens corresponding to pepsin and parapepsin II. Parapepsinogen I was not found. Tang and Tang[4] described a zymogen from human gastric mucosa which, after acid activation, yields both pepsin and gastricsin. The properties of these enzymes appear identical to those of the pepsin and gastricsin previously isolated from human gastric juice[5]. Seijffers *et al.*[6] isolated three chromatographically distinct proenzymes from human fundic gastric mucosa. These were designated pepsinogens I, II and III. Extracts of pyloric and duodenal mucosa yield only a single pepsinogen which, under the conditions of investigation, is apparently identical to the pepsinogen I of fundic extracts[6]. Since then, these same investigators[7] have compared the chromatographic behaviour of pepsins with acidified enzymes which had been previously purified as pepsinogen. Such comparison indicates that pepsinogen I yields pepsin I, pepsinogen III yields pepsin III, while pepsinogen II yields a mixture of two pepsins, II*A* and II*B*. It is possible that pepsinogen II, while chromatographically pure, is a mixture of pepsinogens II*A* and II*B*. Seijffers *et al.*[8] have also identified pepsinogens II and III in human urine. The ratio of pepsinogen II and III in urine, in terms of proteolytic activity after activation, apparently reflects the ratio of pepsinogens II and III in gastric mucosa. In a total of twenty-three urines from twelve individuals, pepsinogen I was never identified.

Electrophoresis has had comparatively little use as a means of pepsinogen fractionation largely because of the lack of suitable methods. Analytical electrophoresis has, however, been utilized. Tang and Tang[4], for example, used starch-gel electrophoresis at *p*H 6·5, localized protein with amido-black stain, and showed that the zymogen isolated from human gastric mucosa was electrophoretically homogeneous. After this zymogen had been acidified, electrophoresis revealed two distinct components corresponding in position to the bands of gastricsin and pepsin obtained from human gastric juice. Post-electrophoretic analysis was achieved by proteolytic assay of unstained transverse sections of gel.

Much more extensive use of analytic electrophoresis has recently been reported by Rapp *et al.*[9] and by Kushner, Rapp and Burtin[10]. These investigators adopted the technique of Uriel[11] for the demonstration of proteolytic activity after electrophoresis in agar. This procedure consists of post-electrophoretic immersion of agar plates in a solution of albumin, buffered at acid *p*H, followed by fixation and staining with amido black. The intact albumin fixed by agar is stained by the dye, whereas digested albumin in zones of proteolytic activity remains unstained. By this means four proteases are detectable in gastric mucosal extracts after electrophoresis in agar at *p*H 8·2. These proteases (P) are designated I, II, III and IV in order of decreasing mobility[8]. Immunoelectrophoretic investigations indicate that II, III and IV are

* Present address: Nuffield Unit of Medical Genetics, Department of Medicine, University of Liverpool.

antigenically and immunologically different. Subsequent correlative column chromatography, electrophoresis and immunochemical analysis[10] established that these zymogens possess the properties of pepsinogen. Moreover, at least five electrophoretically distinct enzymes are detected after acid activation. Immunological correspondence could be shown between the acidified and non-acidified forms of pepsinogens II, III and IV as well as between human pepsinogen II and purified porcine pepsinogen.

The objective of our investigations has been to delineate the origin and functional significance of the multiple pepsinogens and their derivative proteolytic enzymes. The immediate purposes of this report are, first, to describe a simple, reliable method for analytic and preparative starch-gel electrophoresis of pepsinogen and, secondly, to indicate that the several pepsinogen components defined by this method differ not only in electrophoretic mobility but also, when activated, in *p*H optima and proteolytic specificity. Comparison of the electrophoretic mobilities of multiple pepsinogens from several species makes possible the provisional suggestion that the several pepsinogens of a species are probably the product of a single gene. If this view is correct, then the differences between several, if not all, pepsinogens of a species presumably arise after the protein chain has been synthesized.

Materials. Whole stomachs were obtained within 10 min of slaughter from two pigs, two dogs and one rabbit. All animals were healthy. The dogs and the rabbit were killed with intravenous pentobarbital, the pigs at the abattoir. Human gastric mucosa was obtained, at surgery, from an individual with a pre-pyloric ulcer. Mucosa removed from the most proximal and distal portions of this specimen corresponded histologically to fundic and pyloric mucosa respectively.

Random urine specimens were collected from four pigs, three cows and three dogs. Initial morning urine specimens were obtained from two healthy humans. Specimens were promptly brought to *p*H 7·5 by addition of EBT buffer[12] (*vide infra*). After they had first been centrifuged to remove solid matter all urine specimens were maintained at 3° C until used.

Crystalline porcine stomach pepsinogen, *B* grade, lot number 108363, was purchased from Calbiochem, Los Angeles, California.

Preparation of gastric mucosal extracts. Stomachs were opened immediately after collection, washed with chilled isotonic saline, and placed on ice. Within 1 h of collection inside a 4° C room, strips of gastric mucosa were removed from the fundic and pyloric ends of each stomach and thereafter stored separately at −20° C. Extracts were prepared by homogenization of 2·5-g wet mucosa and 2 ml. of distilled water in a chilled Servall homogenizer at 50,000 r.p.m. for 3 min. The homogenate was washed into a tube with 2 ml. of water and centrifuged at 40,000*g* for 20 min at 3° C. The supernatant solution was removed, again centrifuged, and stored at 3° C.

Treatment of urine samples. Seventy-five ml. volumes were concentrated at 3° C by ultrafiltration in collodion bags manufactured by Membranfiltergesellschaft, Göttingen. Small amounts of precipitate were removed from the concentrates by centrifugation and the clear supernatant fluid stored at 3° C.

Assay of peptic activity. The method of Sievers and Fischer[13], as modified by Hanley[14], was used. The reactants for assay consisted of 2·5 ml. of 2 per cent bovine haemoglobin (Armour) in 0·01 N hydrochloric acid, 2 ml. buffer solution (*vide infra*), and 0·5 ml. of solution to be assayed. The last was suitably diluted with water until within the range of method sensitivity. Two 2-ml. aliquots were removed immediately after mixing the reactants. Two ml. of 10 per cent (w/v) trichloroacetic acid (TCA) were added to one aliquot which then served as the blank. The second aliquot was sealed, incubated at 37° C for 24 h, and thereafter 2 ml. of 10 per cent TCA were added. The remaining millilitre of digestion mixture was assayed for *p*H. A final reactant mixture *p*H of 1·5–4·3 was obtained by reciprocal alteration of two buffer solution eluants, namely, 0·2 N hydrochloric acid and a solution which contained 0·2 M DL-glycine and 0·1 N sodium hydroxide. Tyrosine-like material in 1 ml. of TCA supernatant solutions was determined after incubation with 2·5 ml. 4 per cent (w/v) sodium carbonate in 0·1 N sodium hydroxide and 0·5 ml. Folin–Ciocalteau reagent (diluted 1 : 3 with water) for 30 min at 37° C. Absorbance was measured at 700 mμ. The difference in absorbance between blank and test aliquots served as a measure of proteolytic activity.

Starch-gel electrophoresis. Vertical starch-gel electrophoresis was usually performed using a *p*H 8·5 buffer containing EDTA, boric acid and *tris*-(hydroxymethyl) aminomethane (EBT) buffer[12]. A few analyses were performed with Smithies borate buffer[15] and with Poulik's discontinuous buffer[16]. Gels contained seven sample slots and each slot had a capacity of approximately 0·08 ml. After being subjected to electrophoresis at 3° C for 11 h at 5 V/cm a horizontal slice of the gel was soaked in 0·06 N hydrochloric acid for 2 h, thereby lowering the *p*H to approximately 2 and converting pepsinogen to pepsin. One section was then developed with amido-schwarz dye[15]. Gels stained with this dye develop a diffuse light blue background due to the residual protein present in hydrolysed starch[17]. This blue background is locally lost, and replaced by visible non-staining white zones wherever there are proteolytic enzymes present, such as activated pepsinogen. The proteolytic activity of such non-staining zones is verified by a method in which bovine fibrin (Armour), previously dyed with indigo carmine[18], is dusted on to the cut gel surface of the remaining slice of the original acid-soaked gel. The gel is then covered with a wad of filter paper moistened with 0·06 N hydrochloric acid, and incubated for several hours. The gel surface is stained blue by liberated dye. A blueprint of such reaction can be obtained by subsequent drying of the filter paper to which zones of blue dye have adhered.

Estimation of molecular sizes. The relative molecular sizes of several components were estimated, first, by the method of Smithies[19] utilizing the principle that electrophoretic migration in starch gels is a function of starch concentration and, secondly, by the filtration method using 'Sephadex *G*-75' (Pharmacia).

Electrophoretic fractionation of pepsinogen. After starch-gel electrophoresis of 0·5 ml. of pepsinogen, the edges of the gel were marked at intervals, and thereafter a thin horizontal slice removed for staining with amido-schwarz. The balance of the gel was kept frozen in order to obviate diffusion. After the zones of proteolytic activity had been identified by staining with amido-schwarz the positions of these zones were referred to the remainder of gel. The gel was then divided into parallel 1/8-in. wide strips. Pepsinogen was eluted from each section by means of concentric electrodialysis[20] in Visking 'Nojax' cellulose casing at 3° C. Fractions were recovered in approximately 7 ml. EBT starch-gel buffer. Elution was essentially complete within 3 h. Serial eluates were then assayed for proteolytic activity at *p*H 2·0 and *p*H 3·5. Recovery was excellent and in many instances considerable dilution was necessary to bring eluate activity within range of the assay method. The amount of pepsinogen present as protein in such fractions was crudely estimated by comparison of proteolytic activity of acid-activated fractions with t[illegible] derived from known concentrations of unf[illegible]orcine crystalline pepsinogen. Table 1. Composition of Insulin–Pepsin Incubants

Insulin *B* chain (mg)	Solvent	Equivalent μg of pepsinogen*	Source of pepsinogen fractions
1	5% formic acid, *p*H 1·9	1	Pig and man
1	5% acetic acid, *p*H 2·9	1	Pig
3	5% acetic acid, *p*H 2·9	5	Pig

* See section *Electrophoretic fractionation of pepsinogen*.

Digestion of insulin B chain by acid-activated pepsinogen fractions. Insulin *B* chain was prepared from crystalline bovine insulin (Lilly) according to the method of Sanger[21] or by the unpublished method of Dintzis and Dintzis. Samples of *B* chain were digested with pepsin obtained by acid activation of electrophoretically prepared fractions of pepsinogen. Fractions examined in this manner were derived from porcine crystalline pepsinogen as well as from the pepsinogen of human gastric pyloric mucosa. Relevant differences between the composition of the various digestions are shown in Table 1. All digestions were incubated for 18 h at 37° C. Thereafter, samples were dried *in vacuo* and subjected to paper electrophoresis at *p*H 6·4 in pyridine–acetic acid–water buffer (10 : 0·4 : 89·6 v/v) for 3·5 h at 35 V/cm under cooled 'Varsol'. Guide strips were cut from the dried completed ionograms and stained with 0·2 per cent ninhydrin in acetone followed by development with chlorine[22]. Bands located in this fashion were eluted with 6 N hydrochloric acid from the unstained remainder of the paper into 10 × 75 mm 'Pyrex' test-tubes, sealed under nitrogen, and hydrolysed for 18 h at 100° C. Hydrolysates were dried *in vacuo* and subjected to electrophoresis in formic acid buffer *p*H 1·85 (ref. 23) for 2 h at 35 V/cm under 'Varsol'. Dried ionograms were developed with 0·2 per cent ninhydrin in acetone and the amino-acid composition of the hydrolysate thereby determined.

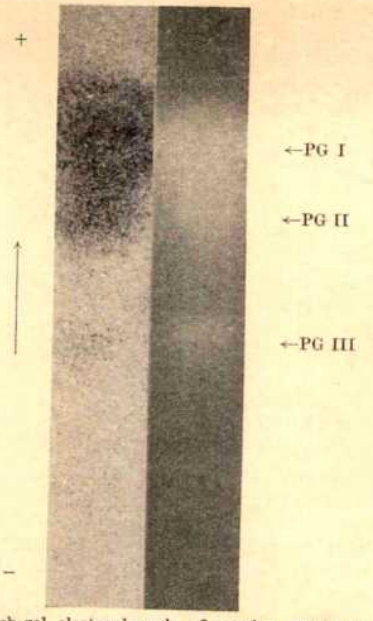

Fig. 2. Starch-gel electrophoresis of porcine crystalline pepsinogen developed, on left, by the method of proteolysis of dyed fibrin and, on the right, by negative staining with amido-schwarz

Starch-gel electrophoretic heterogeneity of pepsinogens present in pyloric and fundic mucosal extracts from single stomach of pig, human, rabbit and dog is shown in Fig. 1.

The general pattern of the result was similar with a discontinuous buffer[16], with a borate buffer[15], and with EBT buffer. The last was used for most examinations. The gel shown in Fig. 1 was developed with amido-schwarz stain. The activated zones of pepsinogen appear as white unstained areas on the pale-blue background of the gel. When present in large concentrations, such as are present in undiluted fundic extracts, pepsinogen appears as a narrow, positively staining, band surrounded by a white halo. Contaminating, non-proteolytic, proteins appear as darkly stained areas of which the most intense has a mobility equivalent to that of albumin. Use of the dyed fibrin method on mirror images of such gels (Fig. 2) readily confirms the fact that only the white areas contain detectable proteolytic activity.

The various pepsinogens defined in this way are provisionally designated PG (pepsinogen) I, II and III in order of decreasing mobility toward the anode at *p*H 8·5. Porcine crystalline pepsinogen exhibits three bands of which the slowest, PG III, is also the weakest in terms of proteolytic activity (Fig. 9); indeed, it does not always reproduce photographically (Fig. 3, slots 1 and 7). PG III of the pig can, however, be clearly seen in the extract of fundic mucosa (Fig. 1). Pyloric mucosal extracts from pig, human, rabbit and dog give appreciably weaker reactions than fundic preparations of similar wet weight (Fig. 1). In addition to such apparently quantitative differences in activity there are other differences. For example, PG I and II of pig pylorus exhibit approximately equal intensity of development whereas PG I from pig fundus is considerably more intense than PG II. In pyloric extracts of human stomachs the intensity of PG II considerably exceeds that of PG I, whereas in human fundic extracts, as in the pig fundic extracts, PG I is more intense than PG II. In the rabbit pyloric extract, relative intensity of the pepsinogens is such that only PG I was clearly distinguishable whereas in fundic extracts PG I and II have similar intensity. Although dog pepsinogen does not give discrete banding there is an evident difference between pyloric and fundic extracts (Fig. 1). However, subsequent work still in progress is revealing that human gastric mucosa taken from an area confined to within a few centimetres of the pylorus contains [illegible]y a single pepsinogen corresponding in mobility to

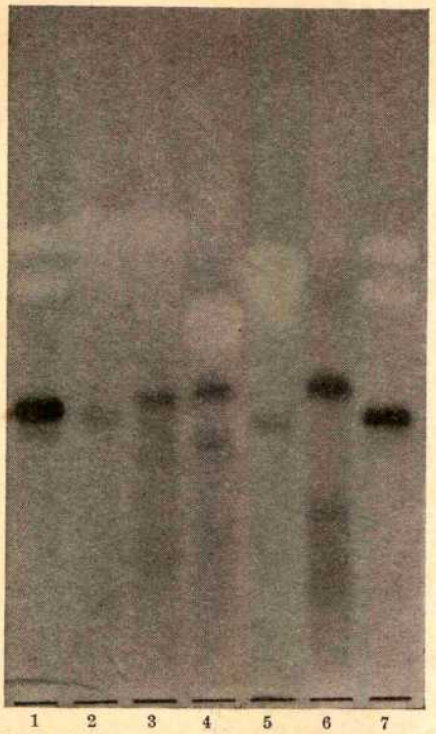

Fig. 3. Starch-gel electrophoresis of urinary pepsinogens from several species. Activated pepsinogens were developed with amido-schwarz stain. Samples shown are (1) and (7) crystalline porcine pepsinogen standard (PG I and PG II are visible); (2) pig urine; (3) cow urine; (4) dog urine; (5) human urine; (6) urine from gastrectomized dog

PG II. Study of distal pyloric mucosa of the other species is pending. Our provisional designation of three principal pepsinogens in man, pig and rabbit must be circumspect since, for example, PG II and PG III of fundic extracts are, in fact, composed of double bands. This phenomenon was consistently reproducible. PG II, derived from either pig or human stomach, showed a greater tendency to be solitary in pyloric extracts than it did in fundic extracts. This was true even when increased concentrations of zymogen were examined. The principal pyloric PG II component consistently corresponded, in migration, with the slower component of fundic PG II.

Although considerable differences in electrophoretic mobility of pepsinogens occur between the species examined, there exists in all species an approximate constancy in the ratio of PG II : PG I migration distances from origin. In fundic extracts the ratio of PG II : PG I migration distances is 0·89 in the pig, 0·90 in man and 0·89 in the rabbit. The respective PG III : PG I ratios for these species are 0·73, 0·77 and 0·73.

Fig. 3 shows the results of starch-gel electrophoresis of concentrated urine from pig, cow, dog and human. Only the pig urine demonstrates two proteolytic components; these correspond exactly to PG I and PG II of the crystalline pepsinogen standard. These two components in pig urine were consistently identified in different preparations of the same urine specimen and in urine from three other pigs. In different urine specimens obtained from one human subject, bands corresponding in position to both PG I and PG II were occasionally seen in both amido-schwarz and dyed fibrin methods of analysis. In other specimens obtained from this same subject only one rather broad band was seen. The leading edge always corresponded in mobility to the leading edge of human PG I obtained from mucosal extracts. The reason for this inconsistency in the demonstration of these two components in human urine is unknown. Dialysis, salting-out procedures with ammonium sulphate, and precipitation of proteins with acetone had no material effect on such results. When the urine of dogs was examined, one animal, although considered healthy, was found to have no demonstrable pepsinogen. A second dog had had a total gastrectomy and demonstrated no pepsinogen bands. Results for urine from a third dog are shown in Fig. 3.

In the species examined there were no differences which could be attributed to the sex of the subject. On no occasion was a third band, corresponding to PG III of the gastric extracts, observed in urine. The proteolytic activity and the electrophoretic pattern of pepsinogen, whether from urine or mucosal extracts, were not influenced either by freezing at −20° C for 3 weeks or by storage at 3° C for 6 weeks.

Characterization of PG I and PG II from Man and Pig

(1) *Relative molecular size.* The relative electrophoretic migration of PG I and PG II derived from porcine crystalline pepsinogen remained constant in gels of varying starch concentration[19], thereby suggesting similarity in the molecular size and shape of these two zymogens. Such a result excluded a monomer–dimer relationship between PG I and PG II. The fact that both pepsinogens are recoverable only from the internal volume of 'Sephadex *G*-75' (Pharmacia) (developed in dilute EBT buffer) corroborates this view. Dimers of pepsinogen would have a molecular weight of twice 45,000 and thus be excluded from the internal volume of 'Sephadex *G*-75'.

(2) *Electrophoretic isolation and purification of individual pepsinogens.* A representative proteolytic assay of acid-activated fractions recovered by starch-gel electrophoresis is shown in Fig. 4. Unactivated fractions of PG I and PG II, obtained in this way, were concentrated fifty-fold by ultrafiltration and re-examined electrophoretically. In each case, only a single sharply defined band of pepsinogen could be identified. Moreover, re-run preparations were free of extraneous positively staining material such as is apparent in both crude extracts and crystalline pepsinogen, thereby suggesting at least a degree of purification. In this manner electrophoretically homogeneous, partially purified PG I and PG II were prepared from porcine crystalline pepsinogen and from human pyloric mucosa. Human pyloric extract rather than fundal extract was chosen for starting material since pyloric PG II tends to be single rather than double banded as in the case of the corresponding fundal zymogens. Initial attempts to isolate useful amounts of the weakly active PG III from porcine material were unsuccessful.

(3) *Proteolytic activity of activated pepsinogens at various hydrogen ion concentrations.* Variation of proteolytic activity with *p*H was determined for activated PG I and PG II electrophoretically isolated from porcine crystalline pepsinogen (Fig. 5) as well as for activated PG I and PG II isolated from human pyloric mucosa (Fig. 6). In both species activity of PG I is maximal at approximately *p*H 2·0 whereas activity of PG II is maximal at approximately *p*H 3·0. The *p*H activity maxima of human activated pepsinogens are somewhat broader than those of porcine pepsinogen, but otherwise similar. No conclusions should be drawn from the varying degree of proteolysis at the *p*H maxima since dilution was not

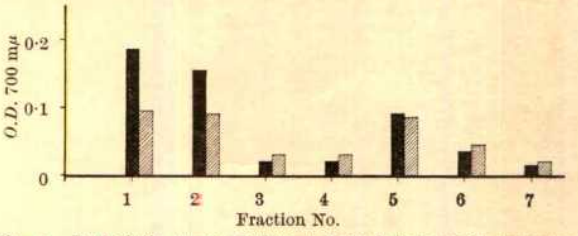

Fig. 4. Proteolytic assay of eluates derived from serial transverse sections of starch gel containing electrophoretically fractionated porcine crystalline pepsinogen. After separation and elution at an alkaline *p*H aliquots of fractions were examined for proteolytic activity (see text) at approximately *p*H 1·9 (black bars) and at *p*H 3·5 (cross-hatched bars). Fractions are numbered 1 to 7 in order of decreasing migration toward the anode. Fractions 1 and 2 correspond to PG I while fractions 5 and 6 correspond to PG II

always comparable and extraction from gel not always complete.

(4) *Digestion of the B chain of insulin by activated pepsinogens.* Ionograms of peptides derived from peptic hydrolysis of insulin *B* chain are shown diagrammatically in Fig. 7. The amino-acid composition and inferred sequence (given the known sequence of *B* chain) of these peptides are shown in Table 2. A comparison of the sites of *B*-chain hydrolysis by pepsin derived from electrophoretically purified preparations of human PG I and PG II and from porcine PG I and PG II appears in Fig. 8. As can be seen, the specificity of PG I and PG II is uninfluenced by species source. However, in both species PG I and PG II produce different patterns of hydrolysis. In either species the principal difference between PG I and PG II appears to be due to a rapid split between the leucine and valine at positions 11 and 12 by activated PG I, but not by activated PG II. Other differences were the selective cleavage between the phenylalanines at positions 24 and 25 by activated PG II and between phenylalanine and tyrosine at positions 25 and 26 by activated PG I. Such differences between PG I and PG II were not influenced by the *p*H at which hydrolysis was performed (Table 1). All our observations are, with a few minor exceptions, corroborative of those described

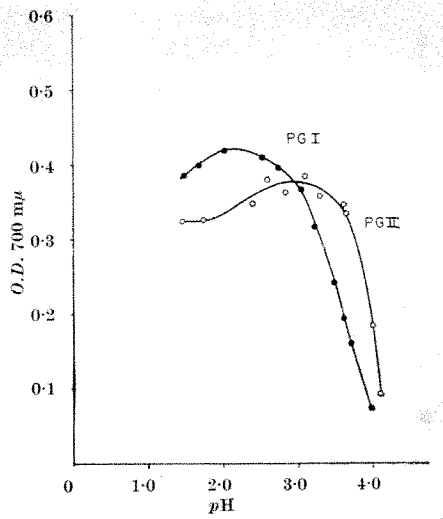

Fig. 6. Influence of *p*H on proteolytic activity (see text) of electrophoretically fractionated pepsinogens obtained from human pyloric mucosal extracts. Closed circles indicate PG I and open circles PG II. PG I aliquots were diluted 1 : 2 before assay of proteolytic activity and the TCA supernatant a further 1 : 4 prior to measurement of absorbance. PG II aliquots were diluted 1 : 8 before assay and thereafter TCA supernatant was diluted 1 : 2

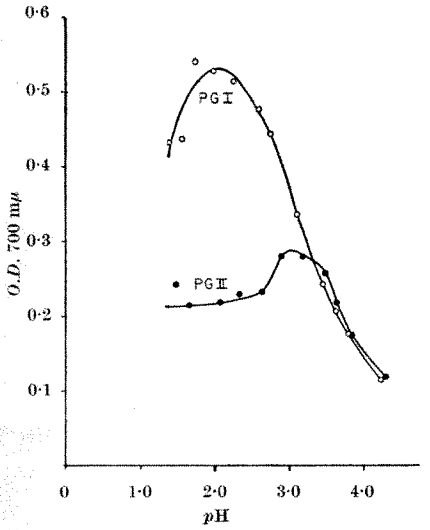

Fig. 5. Influence of *p*H on proteolytic activity (see text) of electrophoretically fractionated pepsinogens obtained from porcine crystalline pepsinogen. Open circles indicate PG I and closed circles PG II. PG I was derived from fractions 1–2 shown in Fig. 4 and PG II from fraction 5

by Ryle and Porter[2] for the digestion of *B* chain by porcine pepsins. The pepsin derived from PG I apparently corresponds to their parapepsin II and the pepsin from our PG II to their parapepsin I.

(5) *Effect of temperature.* Fig. 9 shows the effect of heating on the electrophoretic pattern of porcine crystalline pepsinogen (2 mg/ml. of EBT buffer, *p*H 8·6). Aliquots were heated at 37°, 46°, 55°, 64°, 73° or 82° C for 30 min and thereafter cooled by being plunged into iced water. PG III appears to be the most thermally labile of the three pepsinogens. Its intensity is diminished at 46° C and destroyed at 55° C. At 64° C all three pepsinogens, except for a very small amount of PG I activity, appear to be destroyed. At still higher temperatures, PG I, or something which has the mobility of PG I, survives the treatment at increased temperatures with little or no loss of proteolytic activity. At these higher temperatures PG II and III are replaced by a smear of moderate intensity. This smeared area lies somewhat nearer to the origin than the normal position of PG III. Results such as are shown in Fig. 9 were obtained repeatedly in separate experiments.

(6) *Effect of alkali.* Preparations of porcine crystalline pepsinogen, 2 mg/ml., were brought to *p*H 7·5, 8·3, 9·3 and

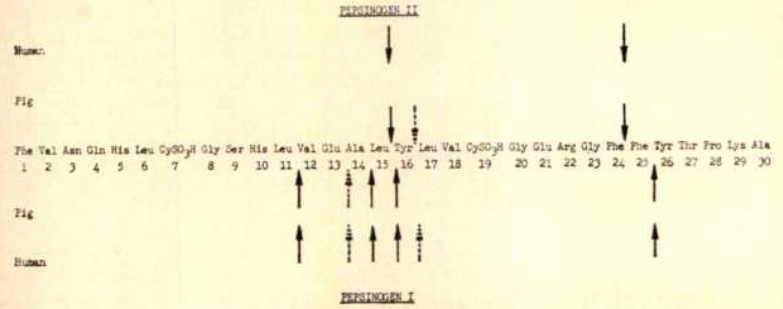

Fig. 8. Sites of digestion of insulin *B* chain by acid activated human and porcine PG I and PG II. Solid arrows refer to principal hydrolytic activities and dotted arrows to minor activities

10·1 with a glycine–sodium hydroxide buffer. After standing at 3° C for 16 h, the solutions were subjected to electrophoresis. From Fig. 10 it is evident that increasing alkalinity results in the destruction of PG III and PG I. PG II, however, persists at *p*H 10·1 although with some diminution of proteolytic activity.

Origin of Zymogen Heterogeneity

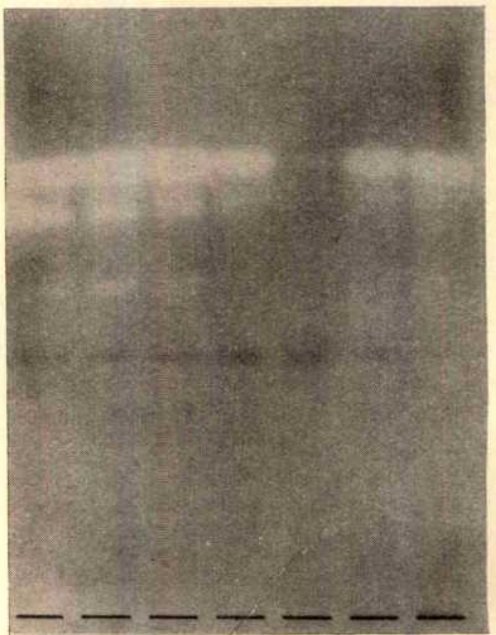
The sum of precedent investigations and our own leaves little doubt that more than one gastric pepsinogen exists. Explanations for the origin of such heterogeneity may, for the sake of discussion, be resolved into two extreme alternatives: either each pepsinogen represents the product of an individual gene or all pepsinogens are produced by a single gene and diversity thereafter created by modification of a single gene product. Precedent for the first of these alternatives is provided by the human haemoglobins. In this instance, four different genetic loci each produce similar but distinctive polypeptide chains[24]. Precedent for the second alternative derives from vertebrate myoglobin where, in each individual, a multiplicity of electrophoretically distinguishable components arise through modification of a single gene product[25].

We favour the second alternative as the origin of pepsinogen diversity and believe that evidence for this view is provided by the approximate constancy, in three species, of the migration ratios PG II: PG I and PG III: PG I. Before interpreting such concordance it should first be recalled that both PG I and PG II are functionally distinctive both in *p*H optima (Figs. 5 and 6) and proteolytic activity (Fig. 8). It is possible, therefore, to identify PG I and PG II in both man and pig by criteria other than electrophoretic mobility and thus eliminate, for example, the possibility that human PG I corresponds to porcine PG II and human PG II to porcine PG I. Accordingly, it appears that the principal difference between the corresponding pepsinogens of man and pig lies in differences in electrophoretic mobility at *p*H 8·5. This difference presumably reflects change in one or more amino-acid residues such that, at an alkaline *p*H, the net negative charge of human PG I is less than that of porcine PG I.

In the event that there are separate genes for PG I, PG II and PG III in both man and pig, then there must have been concordant mutations in all three pepsinogen genes in at least one species so as to allow approximate constancy of the migration ratios PG II : PG I and PG III : PG I. Such concordant mutation demands a good deal of coincidence and leads us to favour the alternative explanation whereby post-synthetic modification of the product of a single gene is the source of zymogen heterogeneity. If correct, the latter explanation provides a source of individual variation beyond that directly specified by a structural gene. Such variation might have biological utility in that it is associated with a more diverse set of functional properties than is evident with only one kind of zymogen.

Although the nature of the postulated modification is unknown it is clear from mobility in starch gels of varying porosity and from 'Sephadex' passage that heterogeneity is not the result of whole pepsinogen polymerization. This conclusion is in accordance with that of Ryle[3], who found the molecular weight of parapepsinogen II to be similar to that of pepsinogen.

It is possible that electrophoretic and functional distinctions between pepsinogens arise in the association of the zymogen molecule with phosphate. The pepsinogen molecule contains one phosphate radical in a diester linkage[26], and it is plausible to believe that this phosphate might, as it does in pepsin, exist as the diester or as the monoester or be absent. In connexion with this possibility it is of interest that three electrophoretically distinctive ovalbumins exist and contain, in order of decreasing mobility, 2, 1 and 0 atoms of phosphorus[26]. It is particularly relevant to the present discussion that incorporation of phosphorus into ovalbumin apparently occurs after polypeptide synthesis[27]. Our preliminary attempts to alter the electrophoretic mobility of porcine crystalline



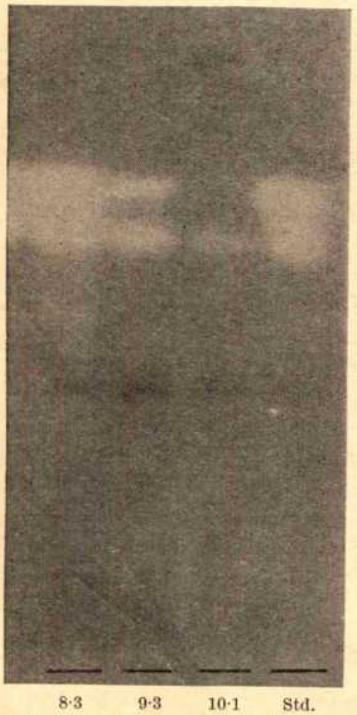


Fig. 9. Starch-gel electrophoresis and subsequent amido-schwarz development of aliquots of porcine crystalline pepsinogen (2 mg/ml. EBT buffer) treated for 30 min at varying temperatures prior to electrophoresis. Figures refer to degrees centigrade

pepsinogen by incubation with partially purified calf intestinal alkaline phosphatase and potato phosphatase were unsuccessful. Success might have depended on contamination of these phosphate monoesterases with small amounts of diesterase and further attempts with other sources of phosphatase might be profitable. Even if not the cause of pepsinogen heterogeneity, it is conceivable that the double-banding of certain pepsinogen fractions (Fig. 1) might be related to the phosphate content.

Irrespective of the origin of such pepsinogen heterogeneity, its functional aspect, as manifest by differential proteolysis of insulin *B* chain, may be useful to investigators of protein primary structure. Although evidence is limited to that from electrophoretic analysis it seems probable that a preparation containing largely the proteolytic characteristics of PG I can be obtained by treatment of crude pepsinogen at 73° C (Fig. 9), while a preparation containing only PG II can be obtained by treatment of crude pepsinogen at *p*H 10 (Fig. 10).

Differences in Zymogen Heterogeneity in Tissues and Fluids

A further dimension of pepsinogen heterogeneity exists between tissues and fluids of an individual. Taylor[28] concluded from a comparison of *p*H activity curves that fundic and pyloric proteases were different. Seijffers, Segal and Miller[6] found only one pepsinogen after chromatography of pyloric extracts whereas three were present in fundic extract. The present investigation also indicates differences between fundic and pyloric mucosa. Our initial results seem to indicate that pyloric mucosa contains two of the three pepsinogen components of fundic mucosa and not one as reported by Seijffers *et al.*[7]. However, subsequent work, still in progress, with human partial gastrectomy specimens is revealing that gastric mucosa from a narrow area adjacent to the pylorus does in fact possess only one pepsinogen corresponding electrophoretically to PG II. It is likely that the pyloric mucosal extracts shown in Fig. 1 contained some fundic type peptic cells. Of the three pepsinogen components of these cells, only PG I shows up—it being the 'strongest'.

8·3 9·3 10·1 Std.

Fig. 10. Starch-gel electrophoresis at *p*H 8·5 and subsequent amidoschwarz development of porcine crystalline pepsinogen which had been subjected to varying alkalinity, for 16 h, prior to electrophoresis. Figures refer to *p*H of treatment

Similarly, although there is no doubt that PG I and PG II both may appear in urine, other investigators[7] find only one. Clearly it is now necessary to utilize several methods, including those of protein composition, to compare the various pepsinogen fractions obtained in several laboratories.

Summary

Pepsinogen, derived from each of several species, may be easily resolved into multiple components by means of alkaline starch-gel electrophoresis. The technique involves acid activation of pepsinogen after electrophoresis and subsequent identification either by digestion of dyed fibrin or more simply by digestion of residual protein present in starch. In the latter method, gels are developed with a general protein stain and peptic activity appears as white non-staining areas on a blue background.

Two principal pepsinogens, PG I and PG II, have been obtained from porcine and from human material by means of preparative starch-gel electrophoresis. Comparison of the configuration of *p*H-activity curves and patterns of insulin *B*-chain hydrolysis obtained after acid activation of these pepsinogens indicates that: (1) PG I and PG II are substantially different functionally as well as electrophoretically; (2) despite inter-species electrophoretic differences there is substantial functional correspondence between PG I of man and pig and between PG II of man and pig.

Comparison of individual porcine pepsinogens establishes that the observed electrophoretic differences are not polymeric by nature. A clue to the origin of the multiple zymogens is provided by a comparison of the mobility of human, porcine and rabbit pepsinogens which indicates that interspecies differences are accompanied, in each species, by approximately parallel changes in the mobility of all principal pepsinogens. Such concordance suggests that the diverse pepsinogens originate, in each individual, through the modification of a single gene product rather than as the products of several genes. If correct, this explanation provides an instance in which functional diversity is extended beyond that which is genetically determined.

A further diverse aspect exists, as there are differences in the number of pepsinogens found in fundic and pyloric extracts, and also in urine.

IMMUNOELECTROPHORETIC PROPERTIES OF LOW-DENSITY HUMAN SERUM LIPOPROTEINS

By Prof. FREDERICK ALADJEM

Department of Microbiology, University of Southern California School of Medicine, Los Angeles, California

THERE is some controversy concerning the immunochemical properties of human serum or plasma lipoproteins. Evidence for immunochemical heterogeneity has been obtained from quantitative precipitin analyses and from immunodiffusion experiments. By means of quantitative precipitin analyses, ultracentrifugally isolated S_f6 and S_f13 lipoproteins were shown to cross-react with anti-S_f6 and anti-S_f13 rabbit antisera, but not to be immunochemically identical[1]. By immunodiffusion in tubes[1] and in plates[2] five or more lipid staining zones of precipitations were obtained. The immunodiffusion data were interpreted to indicate heterogeneity. Gitlin[3] has also reported heterogeneity of lipoproteins (see refs. 1 and 4 for discussion); more recently Lawrence and Shean[5] have reported two and three zones of precipitation by immunoelectrophoresis. Levine *et al.*[6] have used quantitative precipitin analyses and immunodiffusion to study low-density lipoproteins. While these authors interpret the results of precipitin analyses as evidence for homogeneity of lipoproteins, their results do appear to suggest that immunochemical differences exist between the different lipoprotein classes (see ref. 1 for discussion). Evidence for immunochemical homogeneity is based primarily on the finding of only one zone of precipitation by immunodiffusion[4,6], by immunoelectrophoresis[7–9], or by both[10,11].

In view of the continuing reports that only one zone of precipitation forms between low-density human lipoproteins and antiserums[8–11], this article presents the results of immunoelectrophoretic experiments which clearly show multiple zones of precipitation and which also reveal the existence in the S_f17+ fraction of a component with the immunoelectrophoretic mobility of albumin. The status of the immunochemistry of lipoproteins at present is briefly discussed. The available evidence strongly suggests immunochemical heterogeneity of low-density human lipoproteins.

Low-density human serum lipoproteins S_f6, S_f13 and S_f17+, and lipoprotein free serum fractions were prepared and characterized as previously reported[1]. The starting material was pooled fresh serum.

Antisera were produced in rabbits and monkeys. All animals were kept for 6 weeks and bled three or four times during this period to obtain pre-immunization serum. Thirty rabbits and thirteen monkeys (five *Macacus* and eight *Cercopithecus*) were divided into three groups. The first group was immunized with S_f6, the second group with S_f13, and the third group with S_f17+. About 10 mg lipoprotein fraction contained in 0·5 ml. was emulsified with an equal volume of Freund's complete adjuvant. A mixture of freshly prepared lipoprotein and adjuvant was given to each animal twice weekly for 10 weeks. Commencing 3 weeks after the last injection, animals were bled three times at intervals of about 5 days, and were then allowed to rest for 3 weeks. Further courses of injection were then given. Each course consisted of two injections, 5 days apart, of newly prepared lipoprotein fractions plus adjuvant, in quantities indicated here, waiting 2·5–3 weeks and then three bleedings, again at 5-day intervals, and a rest period of 3 weeks. Quantitative precipitin analyses were done by the usual procedure[12].

Immunoelectrophoresis was performed essentially by the technique of Grabar and Williams. The dimensions of the immunoelectrophoretic plates were 10 × 20 × 0·5 cm. Ion agar No. 2 (Consolidated Laboratories, Chicago, Illinois) was used, concentration 0·8 per cent in barbital buffer, $\mu = 0{\cdot}05$, $p\mathrm{H} = 8{\cdot}1$, 0·9 per cent sodium chloride. Rectangular antigen wells 1·5 × 0·3 × 0·5 cm were filled with 0·25 ml. lipoprotein fractions containing 20–30 mg lipoprotein/ml. and 0·8 per cent agar. After electrophoresis, antibody wells were filled with unfractionated antiserums, which contained not less than 1 mg precipitable antibody/ml. (tested with S_f6). Diffusion was allowed to proceed for 28 days. Immunoelectrophoresis plates were stained with sudan black *B*. Immunoelectrophoretic analyses of whole human serum served as immunoelectrophoretic and staining controls.

Ultracentrifugally prepared non-lipoprotein-containing serum fractions were tested by precipitin reaction with the three types of anti-lipoprotein antisera. In no instance was precipitate observed. This finding confirms and extends our previous observations that lipoproteins are antigenically distinct from non-lipoprotein-containing serum proteins[1,13] and served to ascertain that the antisera used were specific for low-density lipoproteins.

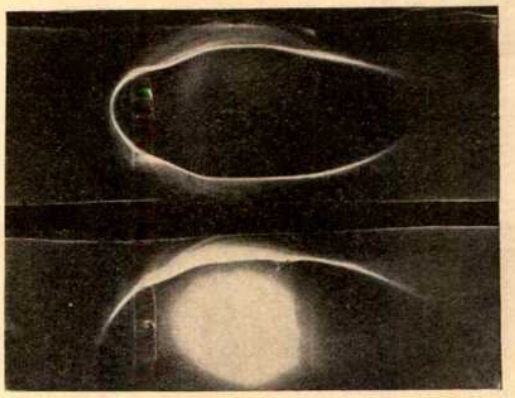

Fig. 1. Immunoelectrophoretic analysis of S_f6 lipoproteins. Upper antigen well: 20 mg/ml.; lower antigen well: 80 mg/ml. Top antibody well, rabbit anti-human serum; centre antibody well, rabbit anti-S_f17+; bottom well, normal rabbit serum

Fig. 1 shows the immunoelectrophoretic results with two concentrations of S_f6 lipoproteins and antisera. Six to eight zones of precipitation can be readily seen, all staining with sudan black *B*. This experiment shows that ultracentrifugally isolated S_f6 lipoproteins are electrophoretically reasonably homogeneous but that several zones of precipitation form which coalesce at the cathodic end. Multiple lipid staining zones of precipitation were similarly obtained with isolated S_f13 lipoproteins and anti-low-density lipoprotein antisera.

The results of immmunoelectrophoretic analyses of S_f17+ lipoproteins and of whole human serum, using several antisera, are shown in Figs. 2–4. Similarly prepared antigen and antiserum preparations were used in these experiments. It can be seen that some of the S_f17+ lipoproteins move with mobility of albumin, some with intermediate mobility, and some, probably chylomicrons, remain at the origin. With the monkey antisera an additional zone of precipitation is observed with certain S_f17+ preparations.

Among the questions which are raised by these results are: (*a*) What is the reason that after more than a dozen reports on immunodiffusion and immunoelectrophoresis of lipoproteins there is not even agreement whether only one zone or several zones of precipitation form between low-density lipoproteins and anti-lipoprotein sera? (*b*) How should the finding of multiple zones of precipitation in Fig. 1 be interpreted? (*c*) What is the significance of the finding that a component in the S_f17+ fraction moves with the mobility of albumin?

The answer to (*a*) may well be found by considering the differences in the experimental procedures in the various investigations. Since we wish to ascertain whether immunochemical heterogeneity exists between or within the different lipoprotein classes, we work with adequately high lipoprotein concentrations and with antisera or antiserum fractions which contain not less than 1 mg

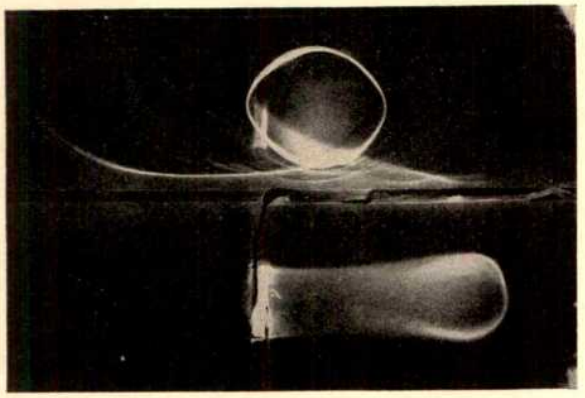

Fig. 2. Immunoelectrophoretic analysis of S_f17+ and serum control. Upper antigen well: normal human serum; lower antigen well: 40 mg/ml. S_f17+. Top antibody well, rabbit anti-S_f17+; centre antibody well, rabbit anti-human serum; bottom antibody well, rabbit anti-S_f17+ (same as in top well)

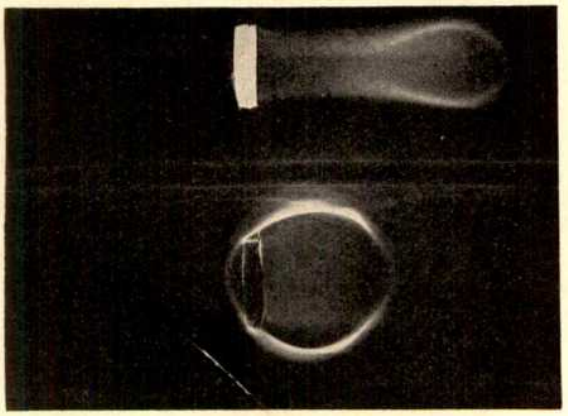

Fig. 3. Immunoelectrophoretic analysis of S_f17+ and serum control. Upper antigen well: 40 mg/ml. S_f17+; lower antigen well: normal human serum. Top antibody well, rabbit anti-S_f17+; centre antibody well, rabbit anti-human serum; bottom antibody well, rabbit anti-S_f17+ (same as in top well)

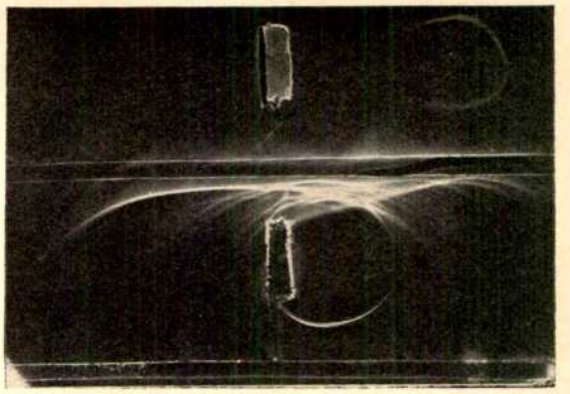

Fig. 4. Immunoelectrophoretic analysis of S_f17+ and serum control. Upper antigen well, 10 mg/ml. S_f17+; lower antigen well, normal human serum. Top antibody well, monkey anti-S_f17+; centre antibody well, monkey anti-normal human serum; bottom, monkey anti-S_f17+ antiserum

antibody/ml., often considerably more. In all the investigations reported in the literature in which only one zone of precipitation was observed, the lipoprotein concentrations were low, approximately those found in normal human serum or less; antibody content is not usually determined. It has been our experience that only one zone of precipitation can be readily obtained if the lipoprotein and/or antibody concentrations are sufficiently low. While we have not rigorously analysed the conditions (concentrations, geometry, etc.) which yield one or multiple zones of precipitation, it appears reasonable to conclude that the discrepancies in the literature are due to differences in the reactant concentrations used in the different investigations.

How can the results in Fig. 1 be interpreted to yield information about homogeneity or heterogeneity of low-density lipoproteins? In recent years a considerable amount of dogma has developed to aid the interpretation of immunodiffusion and immunoelectrophoresis results. A fundamental tenet of this dogma is that multiple zones of precipitation should be independent to be interpretable as evidence for the presence of independent antigen–antibody systems. While this is intuitively reasonable, direct evidence is lacking. The zones of precipitation in Fig. 1 are not independent; the multiple zones fuse into one zone at the cathodic end. Fusion of zones of precipitation has been observed frequently and has usually been interpreted to indicate antigenic similarity or 'partial identity'[14]. Other interpretations have been suggested. Kaminski has observed this type of precipitation (ref. 15, Fig. 6) and has suggested that it may be due either to the same mechanism as that which gives rise to Liesegang rings or to heterogeneity of antibodies. We have observed this type of precipitation regularly only with two types of serum proteins: with albumin and with low-density lipoproteins. We have occasionally (with certain rabbit or monkey antisera) observed it with γ-globulins. On the basis of the work of Kaminski[15] and others[16,17] it has been suggested that "When either antigen or antibody is in great excess the band may widen and even divide into several lines, although the antigen and antibody are pure"[18]. Evidence to substantiate this suggestion is also lacking at the present time; it is not likely that ovalbumin[15], serum albumin[16] or tetanus and diphtheria toxoids[17] can qualify as 'pure'. Twice-recrystallized human mercaptalbumin, for example, has been shown by high-voltage starch-block electrophoresis to contain at least nine components[19]. The Liesegang ring phenomenon is the *bête noire* of immunodiffusion and has sometimes been used to explain away results which cannot at present be explained. So far as I know the Liesegang ring phenomenon is not understood; it is questionable whether it occurs during immunodiffusion. Heterogeneity of antibodies also does not

seem to be a likely explanation, since heterogeneity would also be expected to exist in antibody populations against other antigens and multiple zones of precipitation should then be the usual finding. From these considerations it may be concluded that the most reasonable explanation is that the multiple zones of precipitation indicate heterogeneity of antigen, and that fusion of zones at one end suggests antigenic similarity or 'partial identity'[19]. It may be anticipated that the development of a rigorous analysis of immunodiffusion will eventually clarify such questions, but at the present time we are still attempting to understand the processes which give rise to the initial zones of precipitation[20].

There has been general agreement that low-density lipoproteins move in agar with the mobility of β-globulins while high-density lipoproteins move with the mobility of α-1 globulins. The report by Heide *et al.*[7] suggests that S_f13 lipoproteins have slightly greater mobilities than S_f6 lipoproteins. Walton[8] has recently investigated this problem; he found only very slight differences between mobilities of S_f3–9 and S_f20–400 lipoproteins and attributed these to preferential interaction of S_f3–9 lipoproteins with agar. He noted that the mobility of low-density lipoproteins in agar is somewhat concentration-dependent; a progressive displacement of precipitation zones toward the anode was observed at low lipoprotein concentrations. Our finding that S_f17+ lipoproteins contain a fraction which moves with mobility of albumin was unexpected. S_f17+ lipoproteins certainly contain no material of hydrated density greater than 1·015 g/ml. S_f17+ reacts with antibody against S_f6, S_f13 and S_f17+, but not with antibody against albumin nor with antibody against the lipoprotein-free serum fraction. It is difficult to estimate the concentration of the albumin-mobility material; it would appear to constitute 10–20 per cent of S_f17+. Here again the reason why this fast-moving material has not been previously observed and why it is not observed in Figs. 2–4 in whole serum is almost certainly simply a matter of initial antigen concentration. Not enough S_f17+ containing the albumin-mobility fraction is present in undiluted serum to allow formation of a zone of precipitation.

We are left, then, with the following experimental observations which appertain to heterogeneity of low-density human plasma or serum lipoproteins: (*a*) the finding that antibodies against low-density lipoprotein can be completely absorbed by either S_f6, S_f13 or S_f17+ lipoproteins but that, none the less, S_f6 and S_f13 lipoproteins react differently by quantitative precipitin analysis[1]; (*b*) the multiple zones in Fig. 1 and the immunodiffusion results already cited; (*c*) electrophoretic mobility differences in agar between S_f6 and a component of S_f17+ lipoproteins (Figs. 2–4); (*d*) data from amino-acid end group analyses which show that low-density lipoproteins contain more than one N-terminal amino-acid[21,22]; (*e*) a recent report in abstract form which notes that delipidized low-density lipoproteins contain three protein components by ultracentrifugal analysis and two components by immunoelectrophoresis[23]. These observations, taken together, lend weight to the hypothesis that low-density lipoproteins are immunochemically heterogeneous.

On the basis of immunochemical data, we were previously led to suggest the following antigenic composition of lipoproteins: "Lipoproteins of highest hydrated density, *HDL*-3, are antigenically distinct from all other lipoproteins. *HDL*-2 contain several antigenic components, at least one peculiar to *HDL*-2, others in common with low-density lipoproteins. Continuing the hydrated density scale of lipoproteins towards lower densities, new antigenic components become apparent. Low-density lipoproteins S_f6 and S_f13 contain at least 6 or 8 components. It might be expected that in lipoproteins of still lower hydrated density additional antigenic components may be present, but that some of those associated with S_f6 or S_f13 might be absent. This type of distribution might be thought to exist for lipoproteins up to the chylomicron range"[1]. While, at the present time, the data are still fragmentary, it would appear that the available evidence points in the direction of our early suggestion.

This work was supported by research grant *AI*–0322 and by Career Development award *5K3–GM–4817* from the National Institutes of Health, U.S. Public Health Service.

ESTABLISHMENT OF AN EXPERIMENTAL CAT BREEDING COLONY

By Dr. H. REINERT and G. K. A. SMITH
Department of Pharmacology, Pfizer Ltd., Sandwich, Kent

THE Departmental Committee on Experiments on Animals under the chairmanship of Sir Sydney Littlewood[1] recommends that the Secretary of State should be empowered, subject to consultation with the interests concerned, to prohibit the use of laboratory animals (other than monkeys and animals of farm species) not bred for the purpose in registered laboratories or breeding units outside laboratories.

It is more than likely, therefore, that these recommendations will induce other laboratories to consider the breeding of cats, and the recent increased demand for visiting our experimental and breeding colonies supports this assumption. We feel that our experience in establishing an experimental cat-breeding colony should be of interest to other scientists and laboratories who are using animals for experimentation under the Cruelty to Animals Act, 1876.

An experimental cat-breeding colony was contemplated in Sandwich in 1958 for a number of reasons.

It is a common experience that the supply of laboratory animals, especially cats, is extremely erratic and unreliable. This is based on seasonal breeding peaks and also on the high demand for cats by university departments during term-time. A proper planning of experiments is thus made quite impossible. The great demand and low supply lead in some cases to quite excessive charges by animal suppliers. The condition of cats supplied for experimental purposes is generally extremely poor and it is not uncommon to lose more than 50 per cent of the intake within 1 week before the start of experimentation since most laboratories will quarantine animals supplied from outside sources. This leads obviously to a considerable wastage of already very scarce and expensive laboratory animals. The main cause of death in quarantined cats is respiratory and gastro-intestinal disease.

The poor condition and low resistance of these animals prejudice the performance of lengthy and elaborate experiments under anaesthesia and reduce considerably the success rate. On account of the condition of the animals, experiments have to be repeated unnecessarily, thus again leading to wastage of valuable animals. The scientific value, if any, of experiments carried out on such animals must consequently be very limited. Apart from this wastage of animals, the scientist undertaking the experiment also loses still more of the already limited time available for experimentation. Experiments on animals in poor general condition are thus a highly uneconomic procedure from the point of view not only of the cost of the animals but also of the high cost of the time wasted.

There is, of course, always the risk that, under present conditions when dealers offer or supply large numbers of cats for experimental purposes, the laboratory may be receiving stolen property with all its subsequent legal implications.

We are particularly interested in neurophysiological experiments using *inter alia* stereotactic techniques, and it was thus most desirable to work on a uniform strain of animal which would increase the success rate of accurate electrode placing. A great number of such experiments involves recovery from the anaesthetic, and a good state of health is obviously highly desirable.

For these organizational, economic, scientific and legal reasons it was decided to start at first a small holding colony in Sandwich in the Department of Pharmacology in the summer of 1958. At this time the cats, usually at the kitten stage, were obtained locally, with open knowledge of the reason for their purchase, our object being to keep the animals until they were of a sufficient size and in good physical health for experimental use. Any new intake was inoculated against feline enteritis and was housed indoors within wire-mesh walled rooms some 12–15 ft. sq. in a separate wing of the laboratory building. The cats were fed on a diet suggested by Short[2] consisting of a proprietary food mixed with 'Diet 41' meal with a supplement of cooked fish and reconstituted dried milk for drink.

We experienced the usual trouble associated with a mixed intake-infection—usually respiratory. To overcome and prevent droplet spread a suitable barrier was erected between the rooms instead of the original wire-mesh partitions. A controlled ventilation system was installed connecting to each of the four rooms in which the animals were housed. Many kittens died and those that survived made little headway and were largely unsatisfactory. It was discovered that the haemoglobin content of the animals generally had become very low, in some cases less than 50 per cent of normal values. In an effort to overcome the anaemia, fresh butchers' liver was added to the diet; however, this produced a diarrhoea, but the situation was eased by pre-cooking the liver.

On review, we came to the conclusion that the diet recommended was insufficient to maintain cats, let alone meet the requirements of young growing kittens or support any future breeding, and that an indoor environment was not ideal. Apart from a more adequate diet the animals would most probably improve if they had access to the open air with a natural source of ultra-violet light, as an indoor installation had proved ineffective in controlling airborne germs—or in increasing the animals' resistance to infection.

Late in 1959 the cats were moved outside. Their night quarters consisted of a walled-in area at the base of a water storage tower. Shelves were provided for sleeping accommodation and a trap kept them penned in at night. They were let out daily into a wire-mesh surrounding pen, inside of which were several small alder trees which provided shade and some old tree boughs for claw exercise. The cats were now being fed with liver, fish, tinned cat food, and some potato, and received 'Minadex' in their milk feed. Within a short period an improvement was noticeable.

In the light of our experience and findings plans were going ahead for the establishment of suitable buildings to house breeding colonies of cats and dogs[3] in another area on the Company's site. These were finally completed in the summer of 1961.

The new cat unit is of cavity-walled structure with a screeded concrete floor on 2-in. hollow clay pots, some 120 ft. long by 30 ft. wide with laterally extending external grass runs. Adjoining the building at one end is an annexe housing a preparation room and a toilet. Inside, the floor slopes inwards along the length, to a grilled gulley. A corridor runs along this central line and connects to eight cat rooms on either side. The walls of these cat rooms consist of wire-netting fixed to wood studding and continue upwards to the roof ridge. On either side of each room are open mesh shelves some 3 ft. from the floor with a wooden shelf above. To supply warmth during the cold months a steam-heated pipe runs under the lower shelves. Along the roof ridge four large fans exhaust the inner air to the outside and these are thermostatically controlled to cut out when the inner temperature falls below 58° F.

Each cat room has on the outer wall a draught-proof hinged-exit fitment to allow the cats free access to the outside grass run. This run, 15 ft. wide and 50 ft. long, terminates with a 3-ft.-wide sand pit covering the width of the run which the cats invariably use as a defaecating area (gross material being removed daily by raking). The terminal fence is fitted with a padlocked exit gate. These cat pen runs are constructed of 2-in. tubular metal framework with 1-in. woven-mesh wire 7 ft. high; to prevent escape the whole is covered above with 1-in. chicken mesh wire, supported on wire lacing.

Adjacent to the end of this building are four stud pens, constructed of wood posts with wire-mesh and sited in a row with a communal corridor. Each pen has a sturdy wooden kennel standing 1 ft. high on centrally placed paving squares in a 10-ft. × 8-ft. turfed area incorporating a small sand bed.

As has already been stated, we were buying young cats, mainly weaned kittens, occasionally a complete litter with the mother. The cats were of all colours and fur length but mainly of the tabby variety. Our intention was to select from the short-haired tabby types the nucleus on which to found our breeding stock.

Every new cat was inoculated against feline enteritis and received a booster dose after a year in the colony. It was also assumed that all cats would harbour some form of endo- or exo-parasites and these were routinely dealt with by the customary proprietary treatments and became satisfactorily controlled. In 1962 the unit became a closed colony and since then these parasites have virtually disappeared. However, most, if not all, still harboured respiratory disease agents and by cross-infection became enzootic within the colony with death

resulting in quite a number of animals. With attention to hygiene, antibiotic treatment and general nursing care the immune survivors became the heterogeneous nucleus from which the colony has developed. For breeding we chose only the short-haired tabby types with a well-developed skull and culled for experimental use the long-haired, coloured and narrow-skulled cats.

Originally, for mating purposes some thirty queens were kept together with from two to four toms until the females were obviously pregnant: these queens were then removed to another room. We were hoping to keep manual labour and costs to a minimum by utilizing a communal form of littering down using large nesting boxes instead of small individual boxes or cages. This was not successful as some mothers apparently abandoned their young to a more generous 'mothering' queen for suckling who often supplied sustenance to some fifteen to twenty kittens. Because of several days' difference in the age of the young, the smaller kittens were often pushed out and trampled on and under this local overcrowded environment respiratory virus could and did easily gain a foothold. An isolation technique was adopted by suitably placing six to eight large cat cages within a room. In each cage was placed a cardboard carton with some straw for the pregnant queen to litter down. The queens were allowed out separately for exercise.

As parturition time approaches the queen prepares her nest and shows little interest in leaving the cage. She is disturbed as little as possible by the animal staff, litters occurring naturally with the queens being left to carry on with their instinctive nursing care. Apart from two premature litters occurring in young primipara queens there have been no complications during pregnancy.

Cardboard litter boxes—though sanitarily ideal from a disposal point of view—do involve considerable time in assembly. Often, too, destruction by the queen or the young kittens during the confined period causes the need for frequent replacement: this with large numbers of litters is costly both in labour and materials. Recently we have replaced the cardboard boxes with a chipboard industrial container; these have sufficient weight so as not to topple, stand up well to washing and sodium hypochlorite disinfection (thus allowing repeated use) and stack neatly when not required. It is hoped to try a plastic container—as soon as a suitable box becomes available.

By this isolation technique at littering time one is able to keep infection at a minimum, observe and record individual or litter progress and keep a firm check on their parentage and identity. The litter is kept together for 12–13 weeks (the mother being removed at weaning, 6 weeks); during this confinement the kittens are tattooed by four digits—two in each ear—coded as in a like manner to our dog colony[3]. For example, looking at the cat's face from the front and reading from left to right on the ears the four-digit code $4FH5$ represents 1964 (4): June (F): the eighth litter (H) occurring in that month and the fifth kitten (5) of that litter. This coding allows any member of the departmental staff to identify age, individual and litter mate directly without recourse to any records.

At 5 and 8 weeks the kittens are given an inoculation against feline enteritis, at 10 weeks they are wormed and at 13 weeks are removed from the litter cages, sex segregated into rooms so that the young are approximately of the same age and size, where they stay until they are removed for experimental or other purposes, usually after they are at least 6 months old.

Our cats are extremely tame, and come running for attention when a room is entered, thus making capture easy. This is undoubtedly due to the frequent handling soon after birth by the animal technicians. Apart from the frequent physical inspection, the kittens are weighed weekly for 8 weeks, collectively for the first four and individually thereafter and monthly up to 24 weeks. Weights, together with tattoo coding and other relevant data, are recorded on a breeding record sheet and eventually filed.

Our requirements for experimental purposes are cats of a reasonable size still possessing the vigorous recuperative powers of the young—to be produced, for economic reasons, in the least possible time and weighing 2 kg. The weight curve plotted from the collected data shows that this weight occurs when the animal is between 5 and 6 months. The curve is shown in Fig. 1 and for comparison the weight curves found in cats from two other sources[4,5] are included.

The queen after weaning is wormed and returned to stud, usually with a different tom cat. In this way it is possible to obtain three litters within the year. For example, two queens have produced seven litters, one within 23 months and the other in 25 months.

Between January and December in 1963 and 1964 there were 350 litters, 175 in each year. Fig. 2 shows graphically how these litters occurred month by month with three distinct overlapping peaks of kitten production for each year. This is linked in the lower graph with the average litter size per month, indicating that for this colony there is a tendency for larger litters within the second and third production peaks which occur in the latter half of the calendar year.

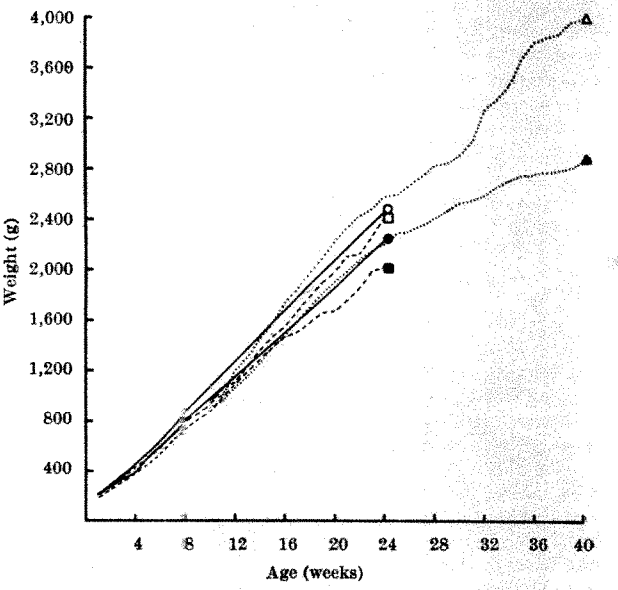

Fig. 1. The graph shows the mean growth curves for male cats (open symbols) and female cats (closed symbols) obtained from three sources. △ and ▲, Short, 200 cats (ref. 4); ○ and ●, Reinert and Smith, 597 cats; □ and ■, Dickinson and Scott, 81 cats (ref. 5)

Normally we expect to take our yield from the first five litters before discarding the queen. By comparing suitable animals with their record it is possible to select the cats most likely to produce good, healthy litters regularly. By using some eighty queens with ten different toms we hope to maintain our requirement and at the same time outbreed as much as is possible within a closed colony.

Breeding losses have been confined to the young, those occurring within the first 3 days and the rest (mainly after weaning) up to about 15 weeks. The kittens up to and included in this period were grouped together after weaning. From the beginning of 1965 the litter has now been confined together for up to 13 weeks before sex grouping and this procedure has so far minimized the losses.

Results for 1963 and 1964 have been tabulated in Table 1 and show the number of litters occurring each month according to the litter size. The combined totals show a normal distribution with a slight shift to the left ranging

Table 1. Numbers of Kittens and Litters born in 1963 and 1964

	Litter totals											Kittens			
	Number of kittens born in any litter										Per month	Mean per litter	Total

Total 1963		7	38	52	41	26	8	1	1	1	175	4·46	781	656	431
1964	2	7	24	53	56	16	12	4	1		175	4·57	800	600	444
1963–64	2	14	62	105	97	42	20	5	2	1	350	4·52	1,581	1,256	875

over from one to ten kittens occurring in a single litter with the mean at 4·52. Losses occurring at birth and during the growing stage lower this mean to 2·5 cats per litter available for experimental purposes—that is, a total of 875 young adult cats from 1,581 kittens born over 2 years, roughly a production of five cats from each breeding female a year. Breeding losses are just more than 40 per cent and it is to be hoped that these can be substantially reduced—although losses almost as high have been found in dog colonies[3] where greater prophylactic measures against infectious disease can be given.

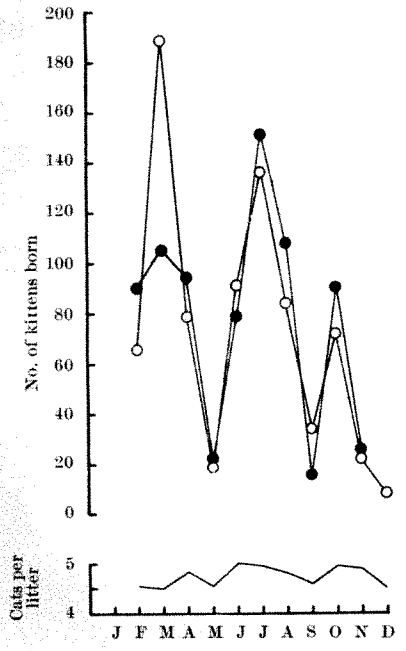

Fig. 2. The upper graphs show the number of kittens born in 1963 (●) and 1964 (○). The lower graph illustrates the average litter size occurring in each month for the combined totals

The colony has been reared on a diet consisting of: 83 parts cooked horsemeat (6 parts offal); 5 parts whole cooked potato; 12 parts 'Terrier' meal; 0·3 parts bone meal, plus salt and dried yeast. All cats have two feeds daily, the main portion being fed in the afternoon.

If the weight curve up to 24 weeks of 597 cats is compared with the findings of Short[4] (who used 200 cats) and of Dickinson and Scott[5] (who used 81 cats) it is found that it occupies a medial position (Fig. 1). The male cats were consistently heavier from the age of about 3 weeks.

Dickinson and Scott showed slightly less kittens born per litter over 5 years, averaging 4·03 kittens for 180 litters producing 727 cats. We have obtained a mean of 4·52 for 1,581 cats; this seems to indicate that our present cooked diet supports reproduction without any lowering of litter size since we are now in our third and fourth generation. We confirm the findings of these workers that a peak production occurs in March and only small numbers in May; however, contrary to their findings, our results reveal a distinct third reproductive peak in the autumn months, which is linked to a third peak in litter size.

Information on losses is remarkably scanty—although it is well known that the cat has a very high incidence of disease, especially of respiratory origin—as many have found to their cost. Until satisfactory vaccinal or other protection is easily and cheaply available, little can be done to change this state of affairs apart from good husbandry and adequate diet. Our 40 per cent loss, in rearing the cats to 6 months of age when they are of practical experimental size, emphasizes the high cost involved in breeding and maintaining these animals, and must reflect the unlikelihood of obtaining at any time well-nourished, parasite-free and reasonably healthy cats in quantity from any source other than from recognized colonies.

Ideally it would, perhaps, be best to start a colony with Caesarian-derived animals, suitably quarantined, to ensure that no infectious agents have passed the placental barrier; and afterwards to breed from these. This is long-term, costly and does not meet the immediate urgent demand; however, this procedure does not prevent the possibility of infection at a later stage, introduced by birds or stray animals when housing cats under open-air conditions.

Animal technicians and other personnel should use rubber footwear to pass through barrier foot-baths and be supplied with adequate clean protective clothing. There should also be provision for hand-washing facilities.

With the introduction of new breeding adults there should be vigorous observance of quarantine, such as separate accommodation remote from the existing colony. It is also desirable that a proof litter should be reared in the same quarters before the adult is finally introduced into the main colony.

Our final advice, based on bitter experience, and in spite of a genuine desire to help those interested in starting cat colonies for themselves, is rigidly to exclude visitors, solely to prevent the disastrous and decimating effects of a fresh introduction of infection.

CYTOGENETIC VARIATIONS INDUCED WITH A MAGNETIC PROBE

By W. C. LEVENGOOD

University of Michigan, Institute of Science and Technology, Ann Arbor, Michigan

EXPERIMENTAL evidence concerning the possible influence of magnetic forces on cytological development in living organisms is, at the present time, in a somewhat controversial state. Several investigators[1–3] have reported a retardation or growth-arresting effect of magnetic fields both at the cellular level as, for example, in carcinoma tissue as well as in whole organisms such as mice. Recently, however, Halpern and Greene[4] found that a 1,200-gauss magnetic field had no significant influence on the growth of human cancer cells (HeLa) in tissue cultures. In most of these reported investigations, the experimental arrangements have been such that the organisms were tested in essentially a homogeneous magnetic field. One finds very few discussions either of the influence of field gradients or of direction and polarity effects.

In proliferating tissue as well as in resting cells, changes in local ion concentration are known to have pronounced effects on general cell morphology[5] and cellular functions. Within a uniform magnetic field the force on an ion is simply charge times the vector product of velocity and field strength. Ideally, under uniform conditions the path described by the ion is circular and motion in a transverse direction is at a minimum. With increasing gradient of flux a lateral ionic drift mobility occurs and the direction of ion flow, although a more complex motion, could, as a result of this additional degree of movement, increase the probability of the field influencing intercellular bonding sites. It is thus conceivable that one might gain additional knowledge concerning the physiological action of magnetic fields on cellular organization by using high localized field gradients rather than striving for homogeneous test regions. This would be especially true if ion-drift mobilities were intimately related to the basic cellular functions.

Based on these considerations, a magnetic probe device was designed to provide an intense, non-homogeneous field in specific regions. This article presents the initial results of subjecting living systems to the probe. In the majority of experiments, the approach has been to apply the magnetic probe to the gonadal organs in *Drosophila melanogaster* at various stages of metamorphosis. The results of the probe treatments are examined in terms of reproductive response effects such as sex ratios, progeny yields and rate of development. Although in the course of these experiments phenotypic variations were observed, extensive crossing tests have not been conducted to determine mutation rates. The main emphasis in this research was placed on examining the question of magnetic fields affecting development and fecundity.

The initial results from the probe tests demonstrate that the application of high field gradients to the developing reproductive organs in *Drosophila melanogaster* has a pronounced influence on development time and on the yield of progeny. A growth retardation effect in an interval of development, including the embryonic and post-embryonic stages, was found to be genetically transferred to succeeding generations even though only pupae producing the first or F_1 generation were exposed to the probe. Viability in the first few inbred generations, as measured by progeny yields, is shown to decrease exponentially with increasing development time; a subsequent increase in sex ratio is suggested. We shall present exploratory data which show variations in the probe influence as a function of pupal age, and we shall also discuss a proposed mechanism based on enzymatic inhibition induced by the magnetic field.

The probe was designed to produce an intense localized field over a region comparable with the diameter of the ovaries and testes in *Drosophila* (approximately 100μ). A coil (5·8 cm long) of No. 34 insulated copper wire was wound uniformly around a 6-mm diameter rod (of low remnant field) with a final resistance of 1,700 ohms (26,770 turns). At one end of this rod a 1-in. section was prepared with a conical taper down to a final diameter of 125μ with the end machined flat. Two parallel connected 22·5 V batteries were used to power the coil and this gave a current of approximately 12 m.amp.

The magnetic field characteristics of this probe were mapped using a model 110 Bell gauss-meter. The effective area on the meter sensor was approximately 1 × 2 mm. The field strength was determined as a function of distance from the probe tip. During calibration, the field contribution from the shoulders of the probe was reduced by extending the tip through a sheet of magnetic shielding metal; 1 mm of the probe was allowed to protrude. Using the ratio of the area on the flat probe tip to the much larger area of the test sensor on the gauss-meter, the effective field strength at the probe surface was determined to be 21·8 ± 1·0 kG. The field gradient within the first 2 mm from the probe tip was approximately 9 kG/mm.

The probe was mounted in a vertical position over a table with a movable stand (glass microscope slide). With this apparatus the specimen could be brought within proximity of the magnetic probe tip, thus allowing treatment of selected portions on larvae, pupae and adult flies. In Fig. 1, a pupa is shown set in position below the probe tip. In the case of eggs, the single egg within the chorion (~ 0·1 mm long) was exposed to the magnetic field.

Using this particular probe design and current load, no significant heating effects were observed for exposure periods of 30 min or more (less than 3 per cent current variation). The current was monitored during each exposure test and the polarity of the probe tip (N. or S. pole) was designated.

Although *Drosophila* were exposed to the magnetic probe in the egg, larval, pupal, and adult forms, the majority of these exploratory data were obtained in the two last-mentioned stages of development. The following general test procedure was used in the probe treatments: (1) With the organism on the movable stage, the glass platform was raised until a 0·5-mm air gap remained between the probe and the test specimen. (2) The field

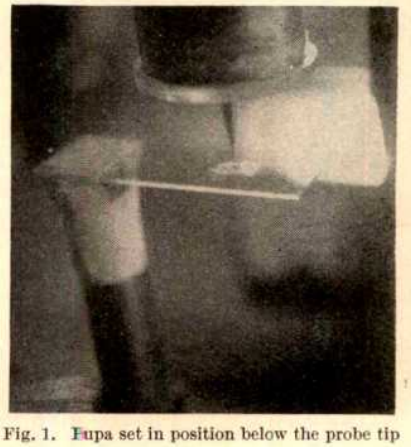

Fig. 1. Pupa set in position below the probe tip

was then switched on for the designated length of time. After the test interval the stage was quickly lowered several centimetres and the test specimen removed from the area before the current was switched off. This was done to prevent transient exposure to a field of reversed polarity. (3) In the case of pupae, the probe was positioned at the dorsal location of the developing reproductive organs. After each exposure the treated pupa was placed with a small segment of the paper on which it had formed into a culture bottle containing fresh medium. (4) Adult flies were anaesthetized with ether and the reproductive organs subjected to the probe treatment. In this case, the probe tests were of short enough duration so that the flies remained anaesthetized and immobile under the probe. The exposures were of 5 min duration or less.

The medium, a cornmeal–molasses type with propionic acid mould inhibitor, was placed in the bottom of 4-oz. culture bottles to a depth of about 2·5 cm. The laboratory temperature was 22° ± 2° C, and both barometric pressure and relative humidity were monitored. Parents were left 10 days in the bottles. Countings were made over an 8-day interval starting with the day the new generation of adult flies were seen.

In most of the test series, three or four generations of flies were examined following the probe treatment; six pairs of flies were randomly selected as the parent stock for each new generation. In some cases where the effects were pronounced, the repeated filial generation crosses were continued for a number of generations. Wherever applicable the usual statistical analyses were used in analysing the data. Control cultures were prepared in the same manner as probe-treated specimens except that a brass 'dummy probe' was applied. The dummy probe was machined to the exact dimensions of the test probe. The exposures to the dummy probe were usually of 10 min duration.

The total period of embryonic and post-embryonic development was taken as the number of days from the start of a new culture until eclosion, that is, when the new generation of adult flies first appeared. Throughout the following sections this interval of metamorphosis will be referred to as the 'development time'. Over the several months during which the probe tests were conducted a total of 52 control (Ore-*R*) cultures were recorded; the mean development time was 13·60 days with a standard error of ±1·12 days (the extreme values were 11 and 16 days).

A mean development time of 13·6 days is somewhat longer than is usually reported in the literature (~ 10 days); however, this reported value does not include the pre-egg-laying period when the flies are introduced into the new culture. Miller[7] recently demonstrated that larval competition in high-density cultures may increase the period of development. This factor was examined by placing single, fertile eggs in fresh cultures. It was noted that imagos appeared after 10–12 days of development; however, a factor of 24–48 h is to be added to this since the usual pre-egg-laying period in the new culture may be several hours (recovery from etherization, etc.) and the eggs may have gone through a maximum of 22 h development before laying. Applying a 1–2 day factor brings the single egg development time within the 11–16 day range of the regular control cultures. It appears, therefore, that overcrowding and larval competition are not factors and the 13·6 day value is a characteristic of this strain (Oregon-*R*). Different strains apparently disclose some variations in development time[7]. The investigations discussed here were all conducted with the Ore-*R* strain.

(1) *Influence on development time.* The probe influence on development time was followed in detail through a number of generation series which were started with treated pupae. In general the development time alteration is inheritable and is not readily selected out of the population. The typical example shown in Fig. 2 was initiated with 110-h-old pupae (six in group) exposed 30 min to the N.-oriented probe. The mean for the previously mentioned 52 control cultures is shown by the heavy horizontal line in Fig. 2 and the shaded area designates the standard error of the mean. Although the individual generation points disclose considerable variability the points lie well outside the statistical values formed by the control group. With succeeding generations there appears to be a general levelling-off effect in the development time; however, it is apparent that the development retardation is not rapidly selected out of the test culture. In the F_7 of this series reciprocal crosses were made with untreated flies from a stock culture. Both test cross-cultures were examined for two generations each, and it was observed that the development time in every case was within the normal range (11–16 days). From these test crosses it may be concluded that the alteration in development time shown in Fig. 2 does not involve a dominant mutant effect.

In some cases the adult flies from the probe-treated pupae produced only one or two flies in the F_1 with development times of more than 20 days. Many pupae formed but did not hatch. This effect was particularly noticeable when treating pupae less than 20 h old. In one case the six adults from 20-h-old pupae, treated 10 min with the S.-oriented probe, produced one F_1 female after a 32-day development time. The remaining pupae in the culture died before hatching.

Even with a brief exposure of only 2 min, an effect on progeny yield was noted, most pronounced from pupae treated in the early stages of growth. The results for two generations are shown in Table 1 for 20-h and 72-h-old pupae tests. Treatment of the 20-h-old pupae increased the development time in the F_1 and in the F_2 larvae formed, but they did not pupate; death occurred after going through the larval stage. Treatment of the 72-h-old pupae did not produce the lethal effect in the second generation, and the development times were within the range of the controls although at the upper limit.

(2) *Response of individual pupa to probe exposure.* To obtain some idea of the male and female response to the probe treatment, a series of single pupa tests were made. The treated pupae were about 37 h old and were given a 30-min exposure. Each treated pupa was placed in a separate culture bottle and, after hatching, was mated with several untreated flies. The probe-treated males were crossed with virgin females from a stock culture. The results summarized in Table 2 demonstrate that only in the case of the male progenitors were the development times altered; however, the influence was not the same in every case. Perhaps it is necessary to treat flies at a definite stage of development to obtain the same results. In these series there could have been a 3 or 4 h variation

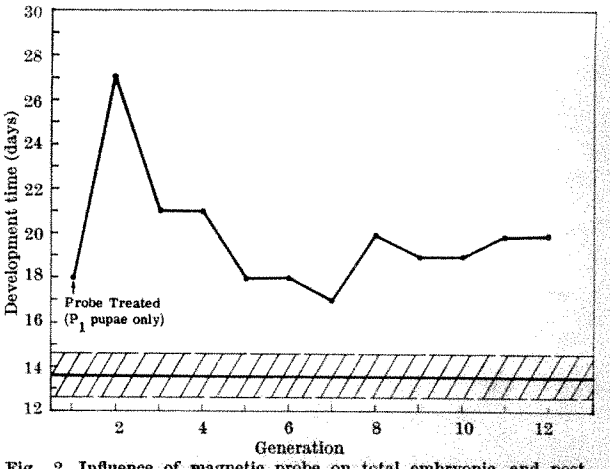

Fig. 2. Influence of magnetic probe on total embryonic and post-embryonic development time (110-h-old pupae–N. probe, 30 min). Mean and standard error for control cultures indicated by heavy horizontal line and cross-hatched area

Table 1. Six Pupae Exposed 2 min with N.-oriented Probe

Generation	20-h-old pupae Total No. progeny	20-h-old pupae Development time (days)	72-h-old pupae Total No. progeny	72-h-old pupae Development time (days)

F_1	86	13	131	14
F_2	115	15	114	16
F_3	0	—	148	14

in the pupal ages and this may account for the different response effects in male pupae given the same treatment. The influence of pupal age is discussed in greater detail in a later section.

(3) *Treatment of adult females.* Three adult female flies were treated 2 min with the magnetic probe after they had been fertilized. After exposure to the probe they were placed in a fresh culture without the presence of males. This ensured that the eggs deposited would be only those treated *in vivo*. The results of this test together with a temporally corresponding control series are given in Table 3. The development times did not appear to be influenced by the probe. In the third generation of the probe-treated series, eggs were deposited but no larvae formed. Many flies in the second generation showed wing abnormalities.

From the 2-min results it was thought that a longer exposure would produce a more drastic effect on the reproductive responses; however, such was not the case. Two groups consisting of three fertilized females in each group were exposed 5 min to the probe using an N. and S. orientation. The groups were examined through four generations and in these series the third generation sterility effect did not appear, and there was no apparent effect on development time.

(4) *Development time alteration through male progenitors.* In one test series, six 21-h-old pupae were treated 10 min with the S.-oriented probe and only five males were hatched in the first generation with a development time of 28 days. These five male flies were crossed with normal untreated females and the development times noted for ten generations. The results are plotted in Fig. 3 and it can be seen that there is a significant increase in the development times. In the third generation the development time was within the control level; however, in the F_4 there was a very sudden increase in the development

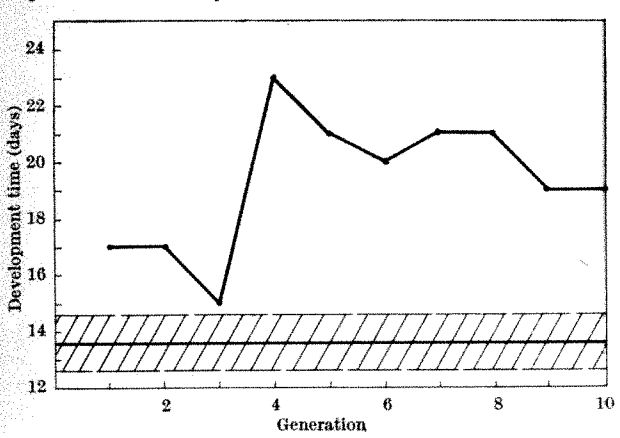

Fig. 3. First generation males from probe-treated pupae crossed with normal females (21-h-old pupae—S. probe, 10 min). Mean and standard error for control cultures indicated by heavy horizontal line and cross-hatched area

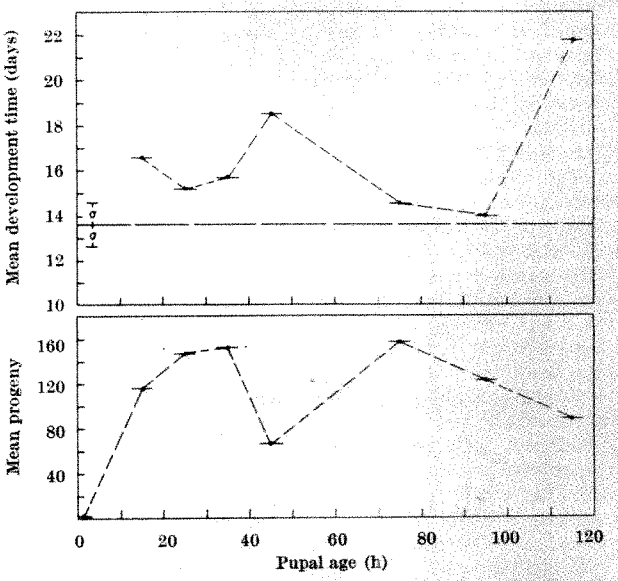

Fig. 4. Variations in development time and progeny with age of treated pupae (points are mean values from four or more generations)

time showing that the effect was not selected out of the culture in the previous generation. This significant increase in development time as carried over by these five males is in contrast with the previous test crossing in the seventh generation of the 110-h pupae (Fig. 2). In this case two generations of reciprocal crosses did not disclose alterations in the development times. From these initial test crosses it appears that the probe effect on development does not follow a simple Mendelian expression.

(5) *Exposure in head region.* More than fifty pupae of various ages were exposed in the head region (10 min treatment—N. orientation). The purpose was to find out if the probe exposure affected an area containing major imaginal disks. This treatment produced a high pupal mortality; more than 50 per cent of the pupae exposed in the head region did not reach the imago stage. Between 5 and 10 per cent of the imagos from head-treated pupae showed severe wing abnormalities and body distortions. Generally the abnormal flies did not live for more than an hour after hatching and crossing experiments were not possible. Possibly the probe influenced the release of growth and development hormones from the brain and corpora allata located near the brain.

(6) *Development, fecundity and age of treated pupae.* Although no attempt was made to investigate explicitly the relationship between pupal age and the probe effect, enough experiments were made at different pupal ages to warrant at least a cursory survey of the results. Data from a number of probe-treated generations were grouped according to the age-level at which they were originally exposed. A 10-h interval was arbitrarily chosen for the test period and both the progeny and development times were tabulated within each age interval.

The mean values for both progeny and development times are plotted in Fig. 4 as a function of pupal age. Each point in Fig. 4 represents from 4 to 20 generations of data and the horizontal lines indicate the age range included. The zero progeny point at the 1-h age-level in the lower curve in Fig. 4 represents a lethal effect. Pupae treated at this early age generally died before hatching.

It is interesting to note that there is an approximate inverse correspondence between development time and progeny. It should be pointed out that all data shown in Fig. 4 represent either singly treated male pupa or the treatment of both male and female pupae. The results of treating a series of female pupae then crossing with unexposed males disclosed no significant change in development time and the fecundity was essentially

unaltered. These results are in accord with the male progenitor effect previously discussed. It appears from Fig. 4 that there are certain stages in the pupal phase of morphogenesis when the organism is more sensitive to the probe treatment than at other stages of development.

In the following paragraphs we shall advance an hypothesis concerning the mechanism of action. We shall show that the ideas suggested, pertaining to the influence of the probe field on living organisms, agree qualitatively and to a limited extent quantitatively with the experimental results in the preceding sections. These concepts are presented with the realization that a demonstration of agreement between experiment and theory does not necessarily rule out other possible explanations for this phenomenon. It is anticipated that as more experimental data are accumulated any hypothetical foundation which might be advanced at this early stage will experience alterations.

Before proposing concepts relating to the probe findings, it is worthwhile to examine the comments of others who have been involved with biomagnetic effects. One of the first positive effects of a magnetic field on enzyme activity was reported by Smith and Cook[7]. The activity of trypsin *in vitro* was found to increase when exposed to a magnetic field. These authors postulated that this effect suggested an increase in the state of organizational order in the enzyme. The energetics of magnetic field–enzyme interactions has also been recently considered by Gross[8]; an observed decrease in antibody formation in a magnetic field was thought to be related to the possible orientation of large protein molecules. Gross pointed out that even though the energy for a flipped electron spin in a 5-k.-oersted field is approximately 1/500 kT at 25° C, this is still of sufficient magnitude to distort the bonding angle of an unpaired electron and it is in the large molecular aggregates that such magnetic effects are possible. Jonnard[9] emphasized that the velocity of a chemical reaction is slowed down if paramagnetic reaction products are formed.

From the foregoing, it does not seem unreasonable to postulate that the magnetic probe increases the free-energy, ΔF, in an enzyme-substrate system. This change in free energy would alter the equilibrium constant, K, of the chemical reaction according to the relation:

$$K = \exp(-\Delta F/RT) \qquad (1)$$

where R is the gas constant and T the absolute temperature. An examination of the data obtained in the probe tests suggests that an alteration in ΔF may have changed the temporal sequence of gene activation during the cyto-differentiation stages (Fig. 4). A determination of these thermodynamic alterations would not, however, reveal anything about the actual reaction mechanisms. For a clearer understanding of probe-induced variations in reaction rates it would be advantageous to examine the chemical kinetics of the effected enzyme systems. It has been pointed out by Wagner and Mitchell[10] that a change in the velocity of an enzymatic reaction of only a few per cent can make a difference in coat colour in the fur of a mammal, or even between life and death of the organism.

If the developmental reactions in *Drosophila* have been effected to the depth suggested in the preceding discussion, then the question remains of what to look for in terms of changes in the reaction kinetics. When examining this point, one turns to the parameters that were observed to be altered by the probe treatment, namely, reproductive yields and development times. As data were accumulated from various series of probe-treated pupae, it became apparent that variations in progeny yields were related to the alterations in development time; this is certainly indicated by the reciprocal nature of the curves shown in Fig. 4.

Conceptually, progeny yields were considered to be an expression of probe-induced variations in enzyme activity within the magnetic field-enzyme-substrate system. The magnetic field-induced inhibition may be expressed by the general equilibrium equation:

$$E + I_m \underset{k_2}{\overset{k_1}{\rightleftharpoons}} E_m \qquad (2)$$

where E is the original enzyme concentration, I_m the magnetic field inhibition, E_m the concentration of the altered enzyme, k_1 the reaction rate of the probe-induced alteration and k_2 the rate of return of the altered enzyme to the original activity.

It appears, however, that this inhibition may be considered irreversible ($k_2 \rightarrow 0$) since the altered enzyme activity E_m is transferred to succeeding generations of flies. At least restoration to the original enzyme activity ($E_m \rightarrow E$) is not significant over the interval commensurate with the period of morphogenesis and k_2 may be taken as zero.

Irreversible inhibition, as pointed out by Webb[11], is expressed by first-order kinetics. The rate of reduction of normal enzyme activity can be written as:

$$-\mathrm{d}E/\mathrm{d}t = k_1(I_m)E \qquad (3)$$

This may then be expressed in the integral form:

$$\int_{E_0}^{E_m} (1/E)\mathrm{d}E = k_1(I_m)\int_0^t \mathrm{d}t \qquad (4)$$

and after performing the integration the following relationship is obtained between the altered enzyme concentration and reaction time:

$$E_m = E_0 \exp(-k_1(I_m)t) \qquad (5)$$

where E_0 is the initial concentration. This initial concentration of enzyme E_0 represents the concentration when the probe is applied to the organism. The value of E_0 is not the same for each probe-treated series but depends on the stage of post-embryonic development (Fig. 4). The change in this initial concentration brought about by the probe treatment induces an alteration in the development rate.

From equation (5), the validity of the foregoing assumptions can be examined by plotting the logarithm of the progeny yields against the development time. The production of offspring reflects the degree of success of various enzymatic reactions, particularly developmental enzymes involved in morphogenesis. It does not seem unreasonable, therefore, to postulate that progeny yields in the probe-treated series are an expression of the altered enzyme E_m and that development time is directly related to k_1, the reaction rate. In Fig. 5 the mean values for a number of four generation series indicate experimental agreement with the equation (5) relationship. The solid square at the left of the curve gives the mean and standard deviations for the 52 control cultures. The scatter of the data

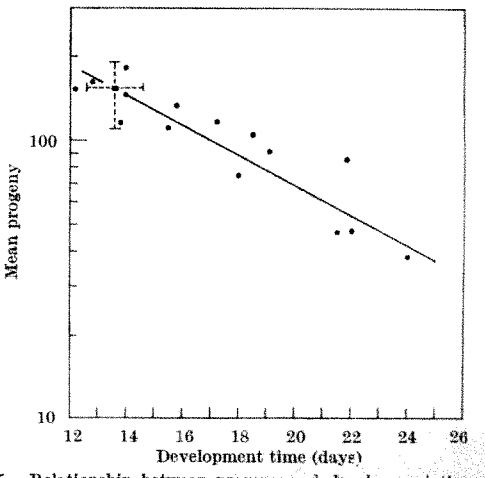

Fig. 5. Relationship between progeny and development time; points represent means of four-generation series treated with magnetic probe in pupal stage of first generation (solid square and dashed lines represent mean and standard deviations of 52 control cultures)

points in Fig. 5 may be attributed primarily to fluctuating environmental conditions. Although local factors such as diet, laboratory temperature, etc., were maintained constant, it has been demonstrated by Levengood and Shinkle[12] that variations produced by 'external' effects such as solar flares may influence *Drosophila* fecundity. These external environmental parameters were not constant over the several months during which the data in Fig. 5 were accumulated.

From the data in Fig. 5 the supposition is made that the ratio of altered to unaltered reactant species (E_m/E_0) is a controlling factor in determining the final progeny yield. An increase in the development time suggests that in terms of relative enzyme activity $E_m < E_0$ following the probe treatment; the active fraction may be expressed by:

$$i = 1 - \exp(-k_1(I_m)t) \quad (6)$$

From the relationship postulated between progeny yields and this fractional activity, the specific rate of inhibition from the Fig. 5 data is:

$$k_1 = 0{\cdot}146 \times 10^{-5}\ \text{sec}^{-1} \quad (7)$$

If introduced at the sensitive periods of metamorphosis, the inhibition seems to have a pronounced effect on the development cycle. Such an inhibition, once established, becomes an inheritable factor, traceable through an increase in the total period of embryonic and post-embryonic cytodifferentiation (Figs. 1 and 2).

A further relationship between alterations in development time and fecundity of the organism was shown in an examination of sex ratios. The mean values for a number of four-generation series are shown in Fig. 6 with the probe orientations designated. There is considerable scatter in the data and the dashed line was sketched in merely to show the trend. This indicated increase in sex ratio may also be related to the altered enzyme reaction kinetics. In this as well as in the previous series there appears to be no marked influence of probe orientation. From the previous considerations of free-energy changes resulting from molecular orientation, it might be expected that the N. and S. orientations on the probe would produce similar effects. One would anticipate polarity differences only in the case of large anisotropies in the molecular dipoles. If such anisotropy exists, the present data indicate that the effect is not pronounced.

At this stage of the experimentation one can only make speculations concerning the type of genetic inheritance primarily involved in the alterations of development time and fecundity. Tentatively, from the manner in which development time alteration is transmitted to succeeding generations and results from a limited number of test crosses, the presence of a cytoplasmic inheritance is indicated. The concept has been advanced[10] that cytoplasmically inherited characteristics can be induced by changes in reaction rates, and this would be in accordance with the hypothesis of variations in the reaction kinetics. Cytoplasmic changes appear to be instigated more readily than gene alterations. In one respect the data

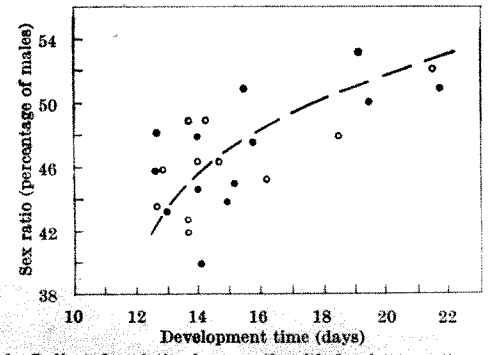

Fig. 6. Indicated variation in sex ratio with development time. Points are means from four generation series (probe treated in pupal stage of first generation. ●, N.-oriented probe; ○, S.-oriented probe

presented in the preceding sections are in disagreement with present-day knowledge concerning mechanisms of cytoplasmic inheritance. Generally, in non-Mendelian inheritance it is the female which carries the effect[10]. A comparison of single-probe-exposed pupae (Table 2) demonstrated, however, that the alteration in development time was initiated through male and not through female pupae. Male adults from treated pupae (Fig. 3) also transferred the increased development time when crossed with normal females, whereas females have not demonstrated any transference when crossed with normal males (occasionally treated females are sterile). The previously reported production of normal genotypes by males has been attributed to the fact that gametes contain very little cytoplasm. The greater volume of cytoplasm in the female egg theoretically increases the probability of cytoplasmically induced mutations. If, as suggested in the mechanism proposed here, the magnetic field through orientation of large molecules reduces the free energy of a small percentage of the enzyme reactants, a small volume of cytoplasm in the sperm could assume greater importance than the larger volume in the female egg. In the sperm we will assume that the percentage of the reactant species per unit volume of cytoplasm is about the same as in the egg cytoplasm. One explanation for the greater effectiveness of the male gamete is the possibility that cytoplasmic bodies in the sperm are in greater proximity with the nuclear material and induced orientation effects could increase the probability of interactions between mitochondria and the nuclear membrane. This in general might explain the greater sensitivity expressed by male-treated pupae.

Perhaps in the 'cramped quarters' of the sperm the magnetic field is operating on fixed-charge systems as described by Ling[13]. In such a fixed-charge system only one species of ion is markedly restricted in motion and presumably in this case the restriction would be on the protein with its associated cations. The anions such as OH^- groups possess a greater degree of freedom in the matrix. The application of the non-uniform magnetic field alters the ionic flow pattern and as a consequence may effect the bonding energy between the protein and its counter ion. One possible site for such an energy alteration is within the interstices of the mitochondria. An induced orientation within the mitochondria may influence the nature of the polypeptide chains and afterwards alter the internal energy control mechanisms. It was suggested by Bourne[14] that the movement of mitochondria may be due to ion pumping and under such conditions the probe could effectively alter ion paths. Such speculations will, however, depend on further experimentation for confirmation or denial.

These initial investigations suggest that the magnetic probe may be important as a technique for producing modifications in cytodifferentiation. This method of locally applying intense field may also be of prime significance in the control or alteration of cell development in carcinoma tissue.

LETTERS TO THE EDITOR

RADIOPHYSICS

Pre-absorption Events at 230 Mc/s

The Type IV radio event of February 5, 1965, was observed with the University of Michigan 28-ft. paraboloid at frequencies of 230 and 345 Mc/s. Following 1847 U.T. many short-duration bursts similar to the 'spike' bursts described by de Groot[1] were observed, superimposed on the continuum at these two frequencies. This communication describes four bursts at 230 Mc/s which were preceded by brief decreases in the background radiation intensity. We interpret these decreases as absorption of the type IV continuum. The four events occurred between 1849 and 1851 U.T. Although numerous bursts occurred at 345 Mc/s, no similar pre-absorptions were observed at this frequency. No instances of post-absorption events were evident on either frequency. Three of the pre-absorption events are shown in Fig. 1. The characteristics of the events are given in Table 1. The flare with which the radio events were associated started at 1750 U.T. and reached a maximum near 1810 U.T. Type IV radiation was observed at metre wave-lengths at Fort Davis from 1800 until 1940 U.T. and at decametre wave-lengths at Boulder from 1810 until 1905 U.T.

Table 1 (see Fig. 2)

Time U.T. (Peak)	t_1 (sec)	t_2 (sec)	t_3 (sec)	t_4 (sec)
(*a*) 18h 49m 13s	0·40	0·10	0·08	0·25
(*b*) 18h 50m 47s	0·45	0·11	0·09	0·25
(*c*) 18h 51m 02s	0·20	0·10	0·06	0·10
(*d*) 18h 51m 04s	0·33	0·07	0·08	0·30

Suspected absorption of solar radio waves has been reported on several occasions[2-4]. The most certain cases of such absorption[2,3] appeared to be associated with active dark filaments crossing the flare regions. Because of the nature of the four events we observed, it seems unlikely

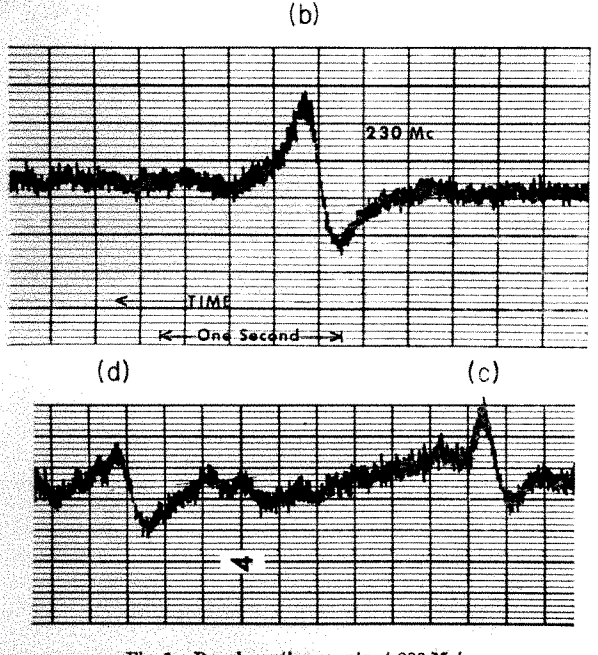

Fig. 1. Pre-absorption events at 230 Mc/s

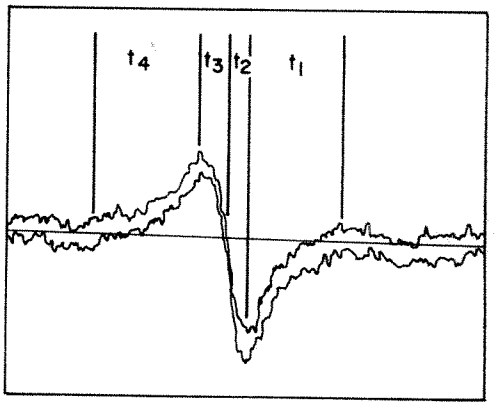

Fig. 2. Event (*b*)

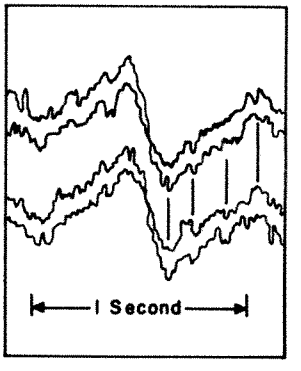

Fig. 3. Event (*d*) shown with its reflexion

to us that the absorptions were due to the drifting of material across the emitting region. The four events exhibit considerable symmetry; the total energy absorbed is comparable with that emitted. Each event is nearly symmetrical about the cross-over point, that is, $t_1 = t_4$, $t_2 = t_3$ (Fig. 2). Moreover, inspection of event (*d*) reveals a curious reflexion of small details about the cross-over. In Fig. 3 the event is compared with its reflexion. It will be noted that three features separated by 0s.13 are found in the falling portions of both the emission and absorption features. The symmetry of these events and lack of post-absorption events tend to rule out scintillations as the source of these phenomena. We are left with the likelihood that true absorption, storage, and re-emission of the radio-frequency energy occurred during these four events.

PHYSICS

Dual- and Multiple-beam Interferometry by Wavefront Reconstruction

THE formation of optical images by wave-front reconstruction as originated by Gabor[1] and more recently extended by Leith and Upatnieks[2] has made it possible to perform interferometry with light reflected or scattered from an irregular three-dimensional object[3]. Some of the possibilities of this method have been discussed in a previous publication[4], and more recently Stetson and Powell[5], Collier, Doherty and Pennington[6] and Brooks, Heflinger and Wuerker[7] have demonstrated several potential applications. This communication reports the successful achievement of multiple-beam as well as two-beam interferometry from the surfaces of standard engineering components. It would seem that many problems involving dilatation of a structure may be investigated in this way.

The principle of the method consists of recording the hologram of an object using coherent laser light, and afterwards replacing the processed hologram plate in its original position in the same apparatus. One then sees the reconstructed image of the object superimposed on the object itself. Any slight change in the surface contours produced, for example, by mechanical strain or thermal expansion will give rise to interference effects between corresponding points on the object and its holographic image, and fringes will be seen to cross the surface.

Fig. 1 shows the experimental arrangement used to produce holographic recording of a piece of steel channel-section girder, and to demonstrate interference effects on distorting it. Coherent light from a helium–neon gas laser is directed through a microscope objective, *O*, which diverges the beam through a suitable angle so that the object is illuminated obliquely. The photographic plate, *H*, now receives an undisturbed spherical wave, together with light scattered from the rough surface of the girder, *G*. The resultant hologram contains sufficient information to reconstruct a three-dimensional image of the girder in exactly the same position as the original.

Fig. 2 shows the appearance, when viewed through the replaced hologram, of the girder after it has been clamped across its webs. Two-beam interference fringes are formed over the surface, their contrast being governed by the relative brightness of the object and reconstructed image, and their number and position on the degree of distortion. The angles of illumination and viewing must also be taken into account for a quantitative assessment.

For a permanent fringe record it is unnecessary to form 'live' fringes between the object and its recorded image. Instead, a double hologram may be made by exposing the photographic plate twice, once with the girder unclamped, and a second time with it clamped. The fringes are now 'frozen' into the photographic recording, and the object, together with the fringes covering it, may be reconstructed without special re-positioning in the apparatus. In fact, it is no longer necessary to use highly coherent light for the purpose, a divergent beam of 'monochromatic' light, for example, from a filtered mercury lamp being sufficient.

An extension of the method of 'frozen' fringes makes it possible to observe multiple-beam interference. Here a multiple-exposure hologram is made with equal increments of strain between exposures. Fig. 3 shows the reconstruction from a five-exposure hologram of the girder. In this experiment the strain was obtained by welding vertical steel bars to the sides of the girder and connecting their upper ends together with a long threaded bolt equipped with a wing-nut and self-aligning washers. Equal turns of the nut then resulted in equal increments of strain in all parts of the structure. The fringe pattern obtained is now a sharpened version of the two-beam interference pattern which would have resulted from a single-strain increment. Three subsidiary interference

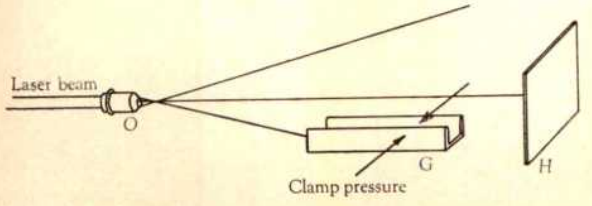

Fig. 1. Experimental arrangement for producing hologram of channel-section girder

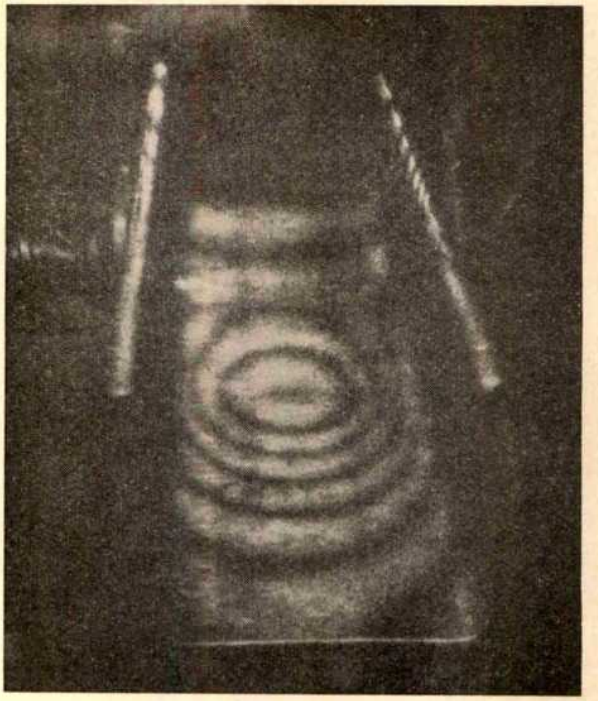

Fig. 2. Two-beam interference pattern on girder due to deformation

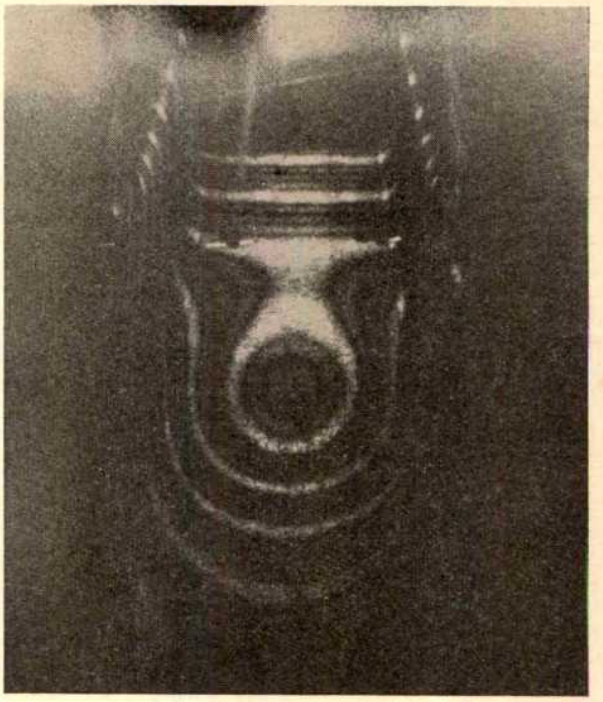

Fig. 3. Five-beam interference fringes from multiple-exposure hologram

maxima are also present between each sharp fringe. With further exposures the main fringes sharpen still further and the subsidiary maxima become weaker. It is also possible to suppress these maxima by an apodization procedure involving only the duration of each exposure.

Sharp multiple-beam effects are obtained only when each individual point on the surface of the object is displaced by equal amounts between exposures. To produce Fig. 3 it was assumed that the structure behaved perfectly elastically, which was borne out in the result. However, if due to overstress, for example, Hooke's law had not been obeyed, the fringes would no longer have been sharp. It is therefore possible that this method could be used to detect weak spots in an engineering component.

CRYSTALLOGRAPHY

Molecular Dimensions and Crystal Structure of Dimethyl Sulphoxide at −60° C

Dimethyl sulphoxide (DMSO) has been much discussed and investigated in recent years because of its remarkable properties in medicine and as a solvent. We have now determined its molecular dimensions and crystal structure, at −60° C, from an analysis of three-dimensional X-ray diffraction data. The sample, being a liquid at room temperature, was enclosed and sealed inside a Lindemann glass capillary of 0·3 mm diameter. It was crystallized, *in situ*, inside a low-temperature Weissenberg camera[1] by slow freezing, melting and refreezing with a jet of cold gas obtained by boiling liquid oxygen[2]. The to-and-fro horizontal movement of the crystal goniometer shaft, involved in this process, was made sufficiently slow and mechanical by coupling the shaft to the spindle of the camera motor by suitable reduction gears. Crossed polaroids mounted on the camera base were used to ensure the quality of the crystal, before single-crystal X-ray pictures were taken. Using copper $K\alpha$ radiation, rotation and hkL (L = 0,1,2,3) equi-inclination intensity data (on multiple films) were collected.

DMSO crystallizes in the monoclinic system, the cell dimensions, at −60 ± 5° C, being a, 11·496 Å, b, 6·742 Å, c, 5·234 Å and β, 95·37° (measured from $hk1$ and $hk2$ photographs by the offset method of Buerger[3]). Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd. The space group is therefore $P2_1/a$. The calculated density, at −60° C, for four molecules in the unit cell is 1·285 g/c.c. and compares well with the liquid density of 1·101 g/c.c. at 20° C.

The x, y co-ordinates were first determined from an M_4 minimum map[4] derived from a sulphur-sharpened Patterson function. They were later obtained independently, together with the z co-ordinates, from a three-dimensional Patterson synthesis. Refinement of the structure was carried out first by $hk0$ difference Fourier maps and then by eight cycles of least squares, with thermal anisotropy

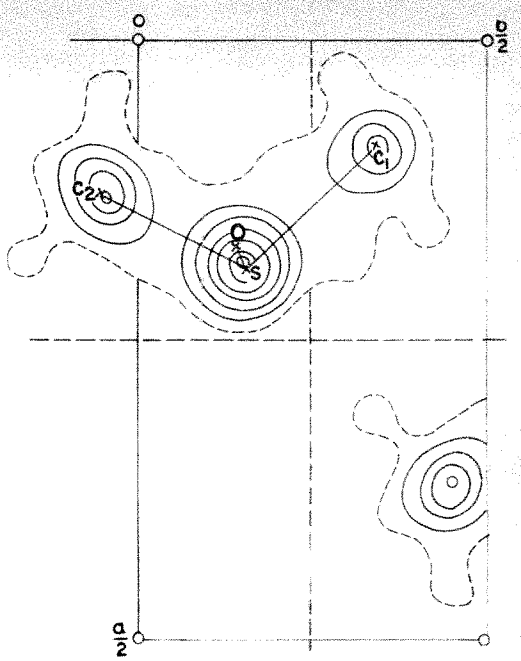

Fig. 1

taken into account in the last four cycles. The final R-factor for all the observed hkL (L = 0,1,2,3) reflexions is 0·129 (R_{hk_0} = 0·104). The final atomic co-ordinates (in fractions of cell edges) with their estimated standard deviations (inside brackets), obtained from Cruickshank's formula, are listed in Table 1.

Table 1

Atom (referred to in Fig. 1)	x	y	z
S	0·1912 (0·0002)	0·1539 (0·0006)	0·6869 (0·0010)
O	0·1711 (0·0006)	0·1365 (0·0014)	0·4060 (0·0024)
C_1	0·0885 (0·0012)	0·3362 (0·0026)	0·7855 (0·0042)
C_2	0·1280 (0·0012)	− 0·0615 (0·0020)	0·8230 (0·0042)

The DMSO molecule has a pyramidal shape with the following dimensions (standard deviations are given inside brackets): S-O = 1·471 Å (0·0080), S-C_1 = 1·812 Å (0·0140), S-C_2 = 1·801 Å (0·0096), C_1-S-O = 107·04° (0·57°), C_2-S-O = 107·43° (0·56°) and C_1-S-C_2 = 97·86° (0·54°). In the case of DMSO vapour, it is found[5] that two molecular models fit the electron diffraction pattern equally well. The present dimensions obtained from the crystal are very close to the averages[5] of the dimensions of these two models. The S-C single bond length in DMSO (1·81 Å) is significantly longer than that found in diphenyl sulphoxide[6] (1·77 Å). This difference is only to be expected as the carbon atom in the latter compound is in the sp^2 state unlike the sp^3 carbon in DMSO.

In the crystal structure the molecules are very closely packed with all the molecular approaches corresponding to those expected for van der Waals interactions. The nearest intermolecular C-C contact is between the centrosymmetrically related C_2 atoms (3·72 Å). Analysis of thermal vibration amplitudes of atoms as well as the location of hydrogen atoms is being worked out.

All the crystallographic computations were carried out on the National Elliott 803*B* computer at H.A.L., Bangalore, using programmes written earlier by one of us (K. K. K.).

We thank Prof. R. S. Krishnan and Dr. N. V. Mani for their advice. We also thank Dr. C. C. Patel for providing the DMSO liquid, Mr. Vijayan for help in collection of

data and Mr. M. M. G. Nambudri for computational assistance.

CHEMISTRY

Electron Spin Resonance Technique for investigating Reactions of Free Radicals with Compounds of Biological Interest: Nucleic Acid Constituents

Earlier, Ingalls and Wall[1,2] reported the use of electron-spin resonance spectroscopy to investigate the reactions of hydrogen and other gaseous free radicals with polymers in a finely divided fluff state. Such fluffs are highly accessible to gaseous free radicals, and react readily to produce polymer radicals which are stabilized by their immobility and separation from one another. Consequently, during exposure to a stream of gaseous atoms, easily observable numbers of polymer radicals rapidly accumulate. A limitation of this technique is that only high-molecular weight materials can be prepared as fluffs. This communication describes a general method of radical stabilization which permits investigation of materials of low molecular weight, and discusses spectra illustrating their application.

The essential feature of the method is the use of quartz wool as a supporting medium. A solution of the material to be investigated is added to a tube containing quartz wool, quickly frozen, and freeze-dried. During the drying process the solute is trapped between the quartz strands to produce a highly dispersed sample. This sample is placed in the electron spin resonance cavity and a gas stream containing atoms is passed over it. Investigations of radical reactions can then be carried out just as with fluffs. The quartz wool has negligible effect on the reactions or the electron spin resonance spectra of the radicals: polyuridylic acid preparations exposed to hydrogen atoms as self-supported fluffs or supported on quartz wool give rise to comparable spectra.

This technique has been used to examine the reactions of hydrogen and deuterium atoms with several constituents of nucleic acids at room temperature[3]. These reactions are of interest because radicals formed by the action of ionizing radiation on thymidine[4,5], thymine[5,6], and DNA[6] all seem to have a hydrogen atom added to the C_6 position of the pyrimidine ring of the thymine part of the molecule. If this interpretation is correct, the same electron spin resonance signal might be expected when hydrogen atoms produced by an electric discharge in hydrogen gas react with these substances.

Such is found to be the case with thymine[7]. The electron spin resonance spectrum of the thymine–hydrogen atom reaction product consists of eight lines (Fig. 1*a*) and is similar to that obtained on γ-irradiation of crystalline thymine[8]. The spectrum of the deuterium atom product (Fig. 1*b*) differs in a way which is consistent with addition of an atom to the molecule. A more complex result is obtained with thymidine[7]. When it is first exposed to hydrogen atoms, the spectrum is similar to that of the thymine product, but with a small singlet component. On continued exposure, however, the spectrum becomes

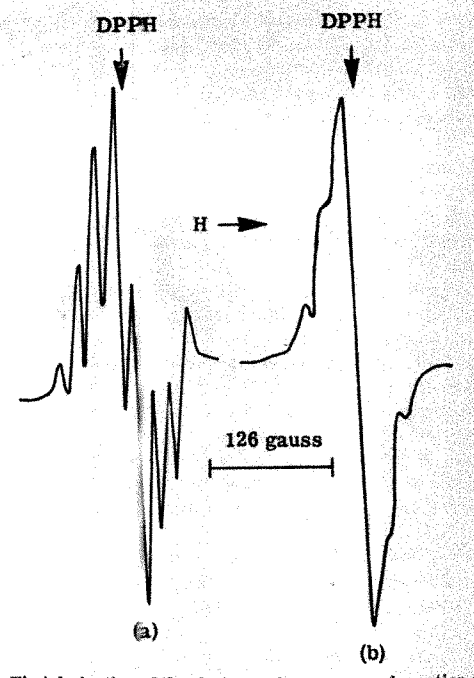

Fig. 1. First derivative of the electron spin resonance absorption spectra of thymine after reaction with (*a*) hydrogen atoms; (*b*) deuterium atoms

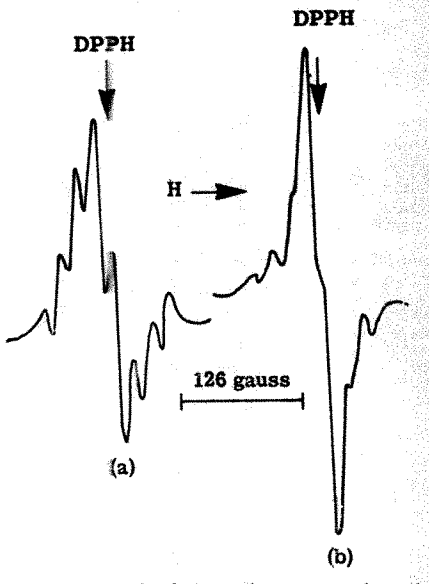

Fig. 2. First derivative of the electron spin resonance absorption spectra of thymidine after reaction with hydrogen atoms. (*a*) Early spectrum; (*b*) late spectrum

similar to the singlet obtained on exposure of deoxyribose to hydrogen atoms, but with a small thymine component (Fig. 2).

Parallel experiments have been done with the uracil family of pyrimidine compounds. Exposure of uracil to hydrogen atoms gives a product with a spectrum similar to that of the thymine product except that the two end lines are absent. Uridine and polyuridylic acid, both of which have a ribose component, behave in the same manner as thymidine. This agrees with the finding that hydrogen atom reactions with ribose and deoxyribose give products with similar spectra. The same late spectra are produced by deuterium atom exposure, suggesting that abstraction from the sugar with the formation of the same radical is occurring.

The details of the sequential change in the spectra of the sugar-containing compounds are not completely understood. It is similar, however, to changes observed during

excited-rare-gas bombardment of polystyrene–polymethyl methacrylate mixtures and co-polymers. In these, the polystyrene product spectrum appears first, but on continued reaction the polymethyl methacrylate product spectrum dominates[9].

The radical build-up in all systems investigated reaches a steady state during the first few minutes of exposure. After exposure the signal intensity remains essentially constant for an indefinite period in a vacuum or an inert atmosphere. However, on admission of dry air it decreases immediately to one-half to one-third the steady-state value, usually without a change in spectral shape; and in ordinary moist room air it is, in most cases, immediately destroyed.

Our present research is directed toward continuing investigations of nucleic acids and their components. This technique is by no means limited to these compounds, however. It should be possible to use it with almost any compound, organic or inorganic, which has a sufficiently low vapour pressure to remain in the cavity during the experiment. With simple modification, such as by using an adsorbing material as a support, it may also be possible to extend the method to include volatile substances as well.

These investigations were supported by the U.S. Atomic Energy Commission through a contract with Atomics International, and through a contract with the University of California.

Graphite–Carbide Materials prepared by Hot-working with the Carbide Phase in the Liquid State

Although processes of hot-working are attractive as a means of reducing the porosity and permeability of graphite, the results of measurements of some of the other physical properties are disappointing[1,2]. For example, bodies hot-worked in compression show some increase in compressive strength parallel to the direction of hot-working, but this gain is offset by a decrease in strength in the perpendicular direction. Although appreciable reductions in the porosity and permeability have been attained, attempts to reduce these properties to negligible values by hot-working to high strain-levels have not been successful.

The work described here is concerned with a new process wherein graphite bodies containing dispersed carbide particles are hot-worked at temperatures such that the carbide phase is in the liquid state. Two carbides have been used, zirconium carbide and molybdenum carbide, with carbide-graphite eutectic temperatures at 2,850° (ref. 3) and 2,584° C (ref. 4) respectively.

The carbide-bearing bodies were prepared by hot-pressing (at approximately 800° C) a dispersion of fine carbide particles in a graphite matrix composed of 80 per cent graphitized petroleum coke and 20 per cent pitch binder; the nominal carbide content was 10 vol. per cent. Using a hot-working device, which is described in ref. 2, these bodies were deformed in compression to strain-levels as high as 60 per cent true strain.

Photomicrographs of graphite bodies containing molybdenum carbide particles are shown in Fig. 1. After hot-working, the graphite matrix is very dense, and the carbide particles are uniformly dispersed with a particle size generally less than 5μ. The carbide content decreases with increasing hot-working strain, the excess liquid carbide appearing as droplets on the surface of the specimen.

Some results for the compressive strengths are given in Fig. 2. These tests were made on cylinders 0·25 in. in diameter by 0·375 in. in height cut with the cylinder axis either parallel or perpendicular to the direction of hot-working. Hot-working of the carbide-bearing bodies results in large increases in strength parallel to the direction of hot-working and modest increases in the perpendicular direction. These effects are in sharp contrast to the results for a similar graphite matrix hot-worked without the carbide additives.

The effective strengthening of the graphite caused by the presence of the liquid carbide phase during hot-working is also shown by the measurements of flexural strength shown in Fig. 3. It should be pointed out that this strengthening is not found when the carbide-graphite body is hot-worked at temperatures such that the carbide phase is solid[2]. The strengthening mechanism appears to be more complex than a simple reinforcement of the

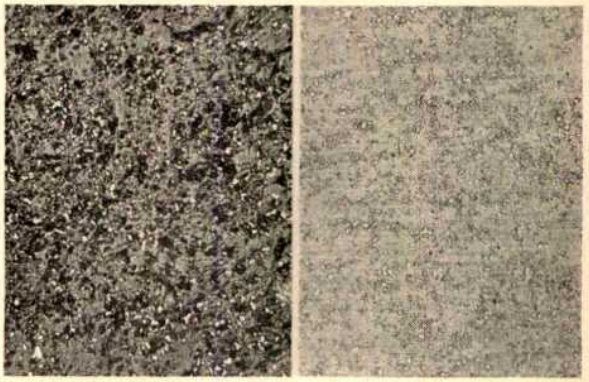

Fig. 1. Microstructures of graphite bodies containing molybdenum carbide particles; left, after annealing at 2,700° C; right, after hot-working to 56 per cent strain at 2,700° C. (× *c.* 120)

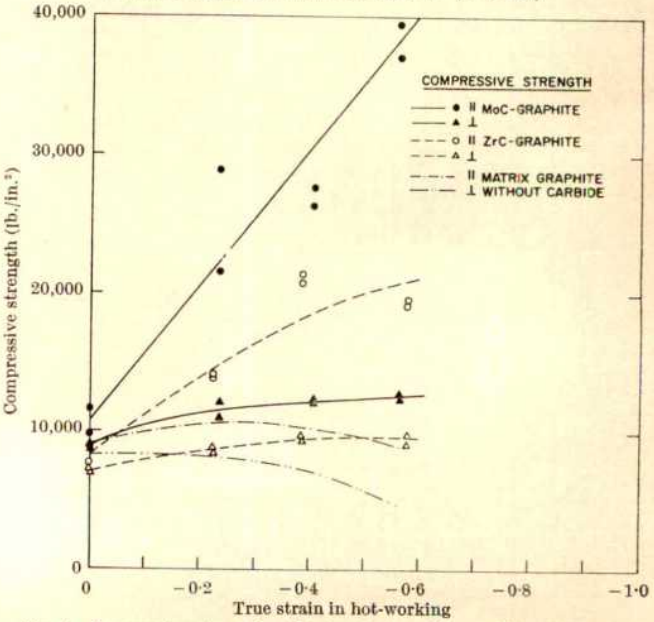

Fig. 2. Compressive strengths of hot-worked matrix graphite with and without a dispersion of carbide particles

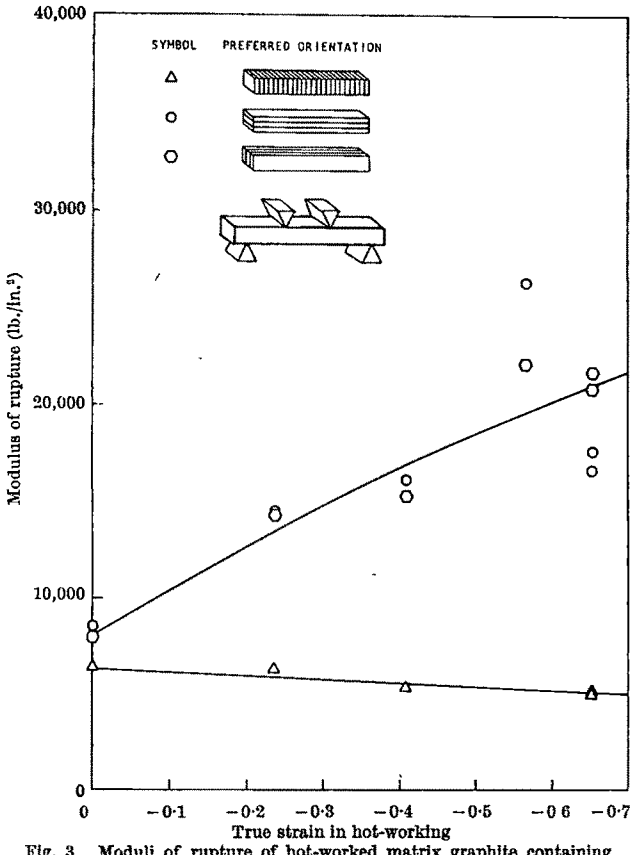

Fig. 3. Moduli of rupture of hot-worked matrix graphite containing molybdenum carbide particles

graphite matrix because the higher strengths are observed for specimens with decreasing amounts of the carbide phase.

Preliminary measurements of the helium permeability of the carbide-bearing bodies hot-worked above the carbon–graphite eutectic temperature indicate that the liquid carbide is effective in blocking pores. The permeability of the starting material is of the order of 2×10^{-4} cm²/sec; when hot-worked, even to modest strain-levels, the permeability is decreased to less than 10^{-6} cm²/sec.

Hot-working with a dispersed liquid phase appears to be a logical development of the concept of liquid-phase sintering[5]. The compressive deformation acts to drive the liquid phase into intimate contact with the porous matrix as well as to reduce the diffusion distances for the sintering process. In contrast to hot-pressing with a conventional piston and cylinder device, the hot-working process affords an opportunity for the excess liquid to escape through a free surface so that the resulting graphitic materials contain only that amount of carbide necessary to plug up the pore structure.

Anharmonic Oscillations in Electrical Potential at Probe Electrodes in Membrane Transport Cells

Forgacs[1] has described experiments which led to the conclusion that steady-state flow may not occur during ion transport through ion-selective membranes. His observations may be summarized as follows. Constant direct current (from rectified power supply or accumulators) was passed through the cell:

$$Ag(s)/AgNO_3\ (0{\cdot}01\ M)/M/AgNO_3\ (0{\cdot}01\ M)/Ag(s)$$

where M is a homogeneous cation or anion exchange membrane. The solutions were stirred at 1,100 r.p.m. Saturated calomel probe electrodes connected through 0·01 M potassium chloride/0·01 M potassium nitrate salt bridges to an oscilloscope were used to measure potential differences across the membrane. It was found that: (1) the observed potential underwent anharmonic oscillation (frequency not stated) about a constant average value; (2) the peak-to-peak amplitude of the oscillations increased with increasing current density; (3) similar oscillations of smaller amplitude were observed when the membrane was removed; (4) similar oscillations of much greater amplitude were observed when the solutions were replaced with 0·01 M silver nitrate in an agar gel.

Observations (1), (2) and (3) have been confirmed in this laboratory, using homogeneous cation exchange membranes between 0·01 M potassium chloride solutions and reversible Ag/AgCl electrodes. It has not been possible to confirm observation (4), however, nor has it been possible to accept the conclusion concerning the absence of steady-state flow conditions. The correct explanation of the observed effects is important, since the use of probe electrodes in membrane experiments is widespread.

Fig. 1 is a sketch of the top half of cell 1. The bottom half was a mirror image of the top, and the cell was operated with the membrane surfaces horizontal. The probe electrodes were chloridized silver wires, and were located in planes distant 2 mm from the membrane surfaces. Cell 2 was simply a 10-mm glass tube provided with four joints which carried current electrodes and probe electrodes (saturated calomel connected through 0·01 M potassium chloride salt bridges). Open tubes opposite the probes permitted the introduction of special stirrers.

In cell 1 it was found that rotation of the drive magnets without the stirrers produced no oscillations in potential at the probes. No oscillations could be detected across a resistor in series with the current electrodes, even when the stirrers were in operation. The frequency of the oscillations was twice the frequency of rotation of one

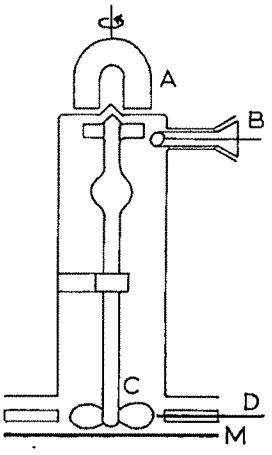

Fig. 1. Membrane transport cell. *A*, Drive magnet; *B*, current electrode; *C*, two-bladed glass stirrer with enclosed magnet; *D*, probe electrode mounted on 'Plexiglass' flange; *M*, membrane

stirrer (180–275 r.p.m.). If two stirrers were used, there were four oscillation peaks per stirrer rotation, unless the stirrer blades were adjusted to pass the respective probe electrodes at the same time. The peak-to-peak amplitude of the oscillations was proportional to current density, and had the value 6·1 ± 0·4 mV/m.amp/cm² of membrane surface between current densities of 0·2–3·0 m.amp/cm². These effects are due, evidently, to an interaction between stirrers and probe electrodes.

Two hypotheses concerning this interaction were tested. The first assumed that there was a large enough potential drop across the probes to establish local concentration gradients. These gradients could then be perturbed by the stirrers, and a perturbation in potential would result. Experiments were conducted (cell 1) in which all but the flattened ends of the Ag/AgCl probes were insulated, and the probes were bent so that their end faces were perpendicular to the direction of current flow. Oscillating potentials of the same magnitude were found, and the hypothesis was therefore rejected.

The second hypothesis was that the stirrer blades distorted the potential distribution near the probe electrodes. A number of experiments supported this hypothesis. (1) When the probes were lengthened and bent so that the uninsulated tips were at least 2 cm from the stirrer paddles, the amplitude of the oscillations was reduced to zero. (2) When the probes were bent so that their tips were within 1 mm of the membrane surfaces, the amplitude was about one-fifteenth of its value with the probes near the stirrer blades. (3) When a stirrer blade was close to a probe and stationary, an extra, constant potential arose between the probes, and disappeared when the blade was moved away. (4) Both insulating and conducting stirrer blades caused fluctuations in probe potential (cell 2).

More direct support for this hypothesis was obtained from equipotential maps constructed to be two-dimensional electrical analogues of the cell. These maps were made on 'Teledeltos' electrically conducting paper, used with copper strip electrodes and a Servomex type *FP*92 field plotter. The maps for two different orientations of insulated stirrer blades are shown in Fig. 2. The change in potential distribution as the stirrer goes from the 'horizontal' position to the 'perpendicular' position is evident, and is sufficient to cause a change in potential at the probe. Similar distortions of the field were obtained using conducting stirrer blades in the maps.

The amplitude of oscillation will be greater with a membrane present simply because of the higher resistance of the membrane and the greater potential drop across it than across an equal thickness of solution. The percentage distortion of the field by the stirrers is constant. Hence, the total amplitude should be proportional to current density. Although this is the case in the experiments reported here, it is only roughly true in Forgacs's experiments. Forgacs used current densities up to 30 m.amp/cm²,

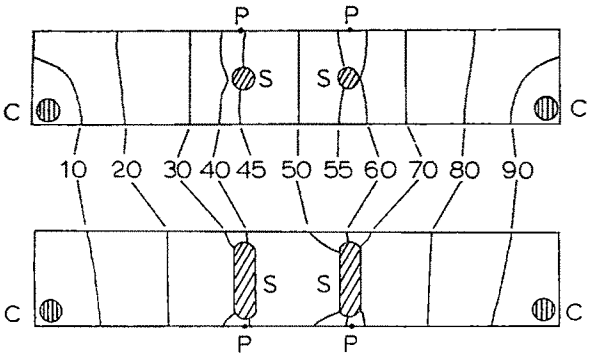

Fig. 2. Two-dimensional potential distributions. *C*, Copper electrodes; *P*, probe positions; *S*, 'stirrers' (holes in paper). Stirrer in 'horizontal' position (below), 'perpendicular' position (above). Numbers are percentage of applied voltage

and it is possible that additional effects due to concentration gradients near the membrane surfaces were encountered by him.

Small, irregular oscillations were observed in cell 2 when it was filled with agar gel, and the current electrodes disintegrated rapidly. For this reason, no relevant conclusions can be drawn from such experiments.

The foregoing experiments demonstrate clearly that unless careful attention is given to the design of stirred membrane transport cells, probe electrode measurements can be misleading. While it is possible to produce small oscillations in potential at the membrane surface, this effect is due to the stirrers, and not to any departure from steady-state conditions inherent in the membrane.

J. W. Lorimer
T. G. Brydges

Department of Chemistry,
University of Western Ontario,
London, Canada.

[1] Forgacs, C., *Nature*, **190**, 339 (1961).

It appears to me that the explanation given by Prof. Lorimer and Brydges is a reasonable interpretation of the results which they obtained with their experimental system. They show that a system incorporating ion-exchange membranes may be subject to oscillations for reasons not associated with the membrane itself. Their reasoning, however, cannot be related to general systems of this type, and certainly not the experimental set-up which I used in my experiments, the results of which were reported in my communication[1].

The differences between the two experimental systems are as follows: (1) The stirrers in my experiments were placed behind the top of the probe electrodes and consequently outside of the potential field between the electrodes and the membrane. In Lorimer and Brydges's experiments the stirrers were placed in such a position that the rotation of the blades was able to affect the potential field between probe electrodes and membrane. (2) Lorimer and Brydges found a correlation between the frequency of potential oscillations and the frequency of the stirrer(s) rotation. Such a correlation would be expected from the experimental arrangement. In my experiment, the oscillations were anharmonic, with randomly changing frequency, and did not appear to be influenced by the condition and rate of stirring. (3) Lorimer and Brydges found a direct proportionality between amplitude of oscillations and current density within the range stated, whereas the results reported by me show no such proportionality at this range. The oscillations become significant only at current densities higher than those which they used.

The fact that the electrical supply system is not described by Lorimer and Brydges makes it difficult for me to evaluate fully their experimental results.

It is regrettable that in the short note I submitted, I did not include some of the details of the experimental procedure given here; however, this was in the nature of a preliminary communication of work which was and is being continued. I did not state or imply that steady-state conditions do not exist in all circumstances, but that they may not necessarily be present. Any theory of ion transport through membranes which assumes *a priori* steady-state conditions may over-simplify the problem.

This work was, and continues to be, part of an effort to elucidate the phenomena of permselective membrane polarization which are not fully explained by existing membrane models. This is being done by investigating unusual aspects of membrane behaviour, finding an explanation for such behaviour and thereby increasing the range of applicability of the model. Several publica-

tions during the previous few years have dealt with such phenomena[2–5]. It was thought, at the time that my first note was published, that the oscillating effect might be a good starting-point for further development. Unfortunately, these effects have presented so complex a picture that I have not yet derived a conclusion worthy of publication, except for an additional short note[6] on the influence of membrane/solution boundary conditions on such oscillations.

Nevertheless, I should like to use this occasion to present a number of generalizations which have been based on observations made during the past few years. (1) The described anharmonic oscillations need not necessarily occur with all types of membranes under all conditions. (2) Generally, such oscillations increase more than linearly with current density. (3) They generally increase in amplitude with time of direct current transfer through the membrane, or may appear after some time of current passage. No case has been observed where the oscillations disappear during current transfer.

I hope that with the continuation of the work, results will be obtained which will provide a wider understanding of the problem, in which event they will, of course, be submitted for publication.

Electronic Structure of the Pt_6Cl_{12} Molecule

IT has recently been found that in addition to the crystal form which consists of ribbons of $PtCl_2$ units, each chlorine being shared by two platinum atoms[1], $PtCl_2$ crystallizes in a form[2] containing Pt_6Cl_{12} molecules which are isostructural with the $Ta_6Cl_{12}^{2+}$ cation[3]. However, these isostructural species are not isoelectronic, the cation effectively having forty valence electrons[4] and the platinum compound seventy-two. In both cases each chloride anion is assumed to contribute two 'σ' electrons only; the four 'π' electrons may, in general, be neglected and assumed non-bonding[5]. The bonding within the $Ta_6Cl_{12}^{2+}$ cation has recently been described in terms of a topological-equivalent-orbital approach[4] and it is the purpose of this communication to extend the treatment to the isostructural platinum compound.

When three precisely equivalent orbitals interact they do so to form a single and a degenerate pair of molecular orbitals. In the present example there are eight sets of three orbitals of this type, one set for each of the faces of the octahedron[4]. These orbitals are a_1b_2e hybrids located on each platinum atom (here we classify the hybrid orbitals by the symmetry species which they span in the C_{4v} local symmetry at each platinum atom; in this way we give more flexibility to the mixing coefficients). When the symmetric combination of a set of these orbitals is the only one occupied, then a three-centred 'face' bond is formed which contributes to the molecular stability. Such bonds are found in the $Ta_6Cl_{12}^{2+}$ cation. If more electrons are fed into each set of three orbitals, then a diamagnetic molecule will only result if four electrons are added. Further, occupation of these three orbitals by six electrons is essentially equivalent to having three non-bonding lone pairs of electrons. This is the situation which exists in Pt_6Cl_{12}, the thirty-two electrons added to the forty in the $Ta_6Cl_{12}^{2+}$ structure occupying anti-bonding orbitals to give a molecule held together by the chlorine bridges alone. This conclusion finds support in the Pt–Pt distance of about 3·4 Å (compare Ta–Ta in $Ta_6Cl_{12}^{2+}$ which is about 2·9 Å).

Clearly, there is little to choose between the two crystal forms of $(PtCl_2)_n$ from the point of view of energy. In both, each platinum is surrounded by four chlorine atoms at the corners of a square and is bonded to neighbouring platinum atoms by them, all other platinum electrons being effectively non-bonding.

Tritium Enrichment by Gas Chromatography

GAS–SOLID chromatography has proved to be a promising method for enrichment of tritium in hydrogen gas samples[1]. Previous work has shown that tritium can be enriched with a concentration factor of about 20 in hydrogen samples of up to 300 ml. and with a tritium loss of up to 5 per cent in a relatively small system. Many problems involving low-level tritium determination, however, require much larger samples of hydrogen (or its equivalent as water) to obtain sufficient tritium for detection and it was, therefore, of interest to see how far the gas chromatographic system could be extended in this direction.

An important primary consideration is the size of the 'low background' counter ultimately intended for the determination of tritium. Two types have been considered here, one of low volume (approximately 40 ml.)[2], which implies the necessity of high concentration factors, and the other of relatively large volume (1·5–2·0 l.)[3] where a lower factor can be tolerated.

In the former case, an apparatus with a three-column system was used[1]. The first column was made of copper tubing with an inner diameter of 10 mm wound in a spiral and with an active length of 2 or 4 m. The second, also of copper, had an inner diameter of 5 mm and an active length of 160 cm, while the third or 'retention' column was a glass capillary of 1·2 mm inner diameter with an active length of 35 or 70 cm. In all cases, activated Linde molecular sieve 5Å was used with a grain size of 0·5–0·8 mm for the first column and 0·3–0·5 mm for the other two. As before[1], the elution-displacement technique was used with helium as the eluting gas and the columns cooled in liquid nitrogen. The results of experiments using various combinations of column lengths are shown in Table 1.

Table 1. TRITIUM RECOVERY FOR VARIOUS THREE-COLUMN SYSTEMS

Experiment	First column (m)	Second column (cm)	Third column (cm)	Sample volume (ml.)	Hydrogen fraction activity (per cent)	Tritium Volume (ml.)	fraction Activity (per cent)	Enrichment factor
1	2	160	35	1,290	1·2	12	98·8	106
2	2	160	70	1,530	0·3	25	99·7	61
				2 000	2 8		97·2	78
3	4	160	35	1,810	1·2	12	98·8	149
				2,120	3·7		96·3	170
4	4	160	70	3,060	3·8	25	96·2	118

It can be seen that 3 l. of hydrogen can be handled with an acceptable tritium loss. The final volume of tritium-hydrogen fraction is defined by the capacity of the third column and was 12 and 25 ml. for the 35 cm and 70 cm columns respectively. Some increase in the size of this third column would probably make it possible to deal with samples of more than 3 l. Any further increase in the size of the first column introduces the technical difficulty of satisfactorily winding copper spiral from large-diameter tubing.

Large volume counters (1·5–2·0 l. capacity) with an acceptable low background have been described and are produced commercially. In this case, a two-column system has proved to be satisfactory. The first column (of glass)

consists of three sections in line—the first two are 50 mm inner diameter and 28 cm long and the third 20 mm inner diameter and 30 cm long. These are connected by short lengths of tubing of 8 mm inner diameter and filled with molecular sieve material with a grain size of 0·5–0·8 mm. The second, or 'retention', column was made of a spiral of copper tubing (5 mm inner diameter) with an active length of 160 cm and filled with molecular sieve material of 0·3–0·5 mm grain size, corresponding to a hydrogen capacity of 900 ml. A specially long Dewar vessel was constructed for cooling the first column and this was lowered automatically over a period of about 100 min. Using a 10-l. sample of hydrogen (corresponding to 8 g of water) a final hydrogen sample of 900 ml. was obtained containing 98 per cent of the tritium. The whole process, including reduction of 8 g of water with magnesium at 600° C, took about 3 h.

By increasing the length of the retention column to 4 m it was possible to process 20 l. of hydrogen, which yielded a final fraction of 2 l. containing 96 per cent of the tritium. In all experiments, a concentration of approximately 0·015 μc. tritium/l. of hydrogen was used.

I wish to thank Dr. G. B. Cook, head of this Laboratory, for many helpful discussions and Dr. M. B. A. Crespi for his advice.

Mechanism of the o-Phenylenediamine Cleavage of Ketones

The thermal reactions of *o*-phenylenediamine with carbonyl compounds have been investigated for a number of years[1–3]. Recently, Elderfield[4–6] has extensively investigated the cleavage of ketones with this reagent, and has found that the reaction affords 2-alkylbenzimidazoles and alkanes in high yields. Investigations of the scope of the degradation have indicated that the more substituted group is eliminated as the alkane[7–9]. The mechanism of this elimination is not, however, known at the present time.

Initial experiments in this laboratory have indicated that benzyl ketones are more readily cleaved than aliphatic or aromatic ketones. This fact has led us to suggest that the initial intermediate, 2-benzyl-2-alkylbenzimidazoline, either rearranges to 1-benzyl-2-alkylbenzimidazoline which then decomposes to the alkane and benzimidazole or degrades to the final products by means of a bimolecular elimination. In an investigation of the former hypothesis, the second intermediate, 1-benzyl-2-phenylbenzimidazoline, was prepared by reacting N-benzyl-*o*-phenylenediamine with benzaldehyde; this compound was then pyrolysed in the usual manner: the benzimidazoline (2·86 g, 0·01 M) was heated in a 'Pyrex' distilling tube. The temperature of the oil bath was raised slowly to 180° C and this temperature was maintained for 12 h. During this time, toluene did not distil from the reaction mixture. After the pyrolysate was allowed to cool, it was washed with methyl alcohol; this treatment gave 1-benzyl-2-phenylbenzimidazole (2·04 g, 72 per cent). It is evident, therefore, that 1-benzyl-2-phenylbenzimidazoline is not an intermediate in the *o*-phenyldiamine reaction.

The latter hypothesis, namely, the bimolecular elimination pathway, was also investigated. This mechanism was suggested because recent investigations[10,11] on the pyrolytic decompositions of esters have indicated a bimolecular pathway, and Elderfield *et al.* have been able to catalyse the cleavage reactions with both acids and bases[6,9]. The latter result has led us to investigate amines and benzimidazoles as possible catalysts in these reactions. These investigations have shown that the decomposition temperature (initial gas evolution) of 2-benzyl-2-phenyl benzimidazoline can be lowered from 235° C to 200° C by adding small amounts of diphenylamine, benzimidazole, 2-phenylbenzimidazole or 2-methylbenzimidazole to the pyrolysis mixture. A typical experiment is as follows: benzyl phenyl ketone (1·06 g, 0·01 M), and 2-phenylbenzimidazole (0·194 g, 0·001 M) were heated in a 'Pyrex' distilling tube. The temperature of the bath was slowly raised to 195–205° C; at this temperature gas evolution was evident. When the reaction was run in the absence of the benzimidazole, the decomposition temperature was found to be 230–240° C. Based on the catalytic activity of these compounds, the mechanism of this reaction may involve a bimolecular elimination that can be formulated in this manner:

BIOCHEMISTRY

Operon Hypothesis: New Evidence from the 'Constant Proportion' Group of the Embden–Meyerhof Pathway

A number of examples have now been reported in which a group of enzymes is synthesized in such a manner that the relative activity of each of the enzymes within the group is constant. An important example of this is the 'constant-proportion' group in the Embden–Meyerhof pathway, which has been extensively investigated by Vogell *et al.*[1] and by Pette *et al.*[2]. These workers examined a wide range of materials, extending from baker's yeast to various mammalian tissues, and found that the activity of the five enzymes, triosephosphate isomerase to enolase, formed a pattern which is quite reproducible. They suggest that this indicates a "co-ordinate control of enzyme synthesis" by the cell at the molecular level, a subject which has been the focal point of much recent attention.

A most significant observation, however, which appears entirely to have escaped notice is that the actual pattern reported by Vogell *et al.* in fact represents equimolar amounts of these five enzymes. In Table 1, column 4 shows the calculated 'activity pattern' of equimolar ratios of the enzymes, and column 5 the findings of Pette *et al.* The figures in both columns are expressed as a ratio to the activity of glyceraldehyde phosphate dehydrogenase. Despite the large cumulative errors which may appear in calculations involving several independent measure-

Table 1. ACTIVITY PATTERN OF THE CONSTANT-PROPORTION GROUP IN THE EMBDEN–MEYERHOF PATHWAY: A COMPARISON OF THE CALCULATED VALUES WITH THE MEASUREMENTS OF PETTE *et al.*

Enzyme	Molecular weight	Specific activity (μmoles substrate/h/mg protein)	Calculated activity pattern	Measurements of Pette *et al* (ref. 2)

Glyceraldehyde phosphate dehydrogenase	1.4×10^{5} (refs. 4 and 5)	5.5×10^{3} (ref. 3)	1	1
Phosphoglycerate kinase	3.4×10^{4} (ref. 6)	1.85×10^{4} (ref. 3)	0·82	0·6–1·2
Phosphoglycerate mutase	5.7×10^{4} (ref. 7)	7.8×10^{3} (ref. 7)	0.58	0.6–1.2
Enolase	8.5×10^{4} (ref. 8)	2.72×10^{3} (ref. 3)	0·30	0.15–0·3

* This is an approximate value obtained in these laboratories by the method of Andrews (ref. 9) using gel-filtration on 'Sephadex *G* 200'.

ments (particularly by different workers), there is a remarkably good correlation between the calculated and the experimentally derived values.

We may conclude, therefore, that the cell necessarily produces molecules of each of these five enzymes in precisely equal numbers. This is of particular interest because the Embden–Meyerhof 'constant-proportion' group appears to be an example of a group of proteins the synthesis of which is controlled by a single 'operator' gene. Although a number of such groups have been investigated, particularly in bacteria[10,11], figures for the stoichiometric relationship of the rates of synthesis of the individual proteins within any particular group have not been published. It is therefore possible that this finding is valid for operon groups in general.

Should this be true, then a considerable simplification may be made to the present model of protein synthesis; namely, that one single molecule of 'messenger' RNA is synthesized from the DNA strand per operon rather than a separate molecule of 'messenger' RNA for each structural gene. This RNA molecule would obviously duplicate the 'commas' presumed to exist on the DNA molecule and would thus induce breaks in the polypeptide chain during the actual protein synthesis.

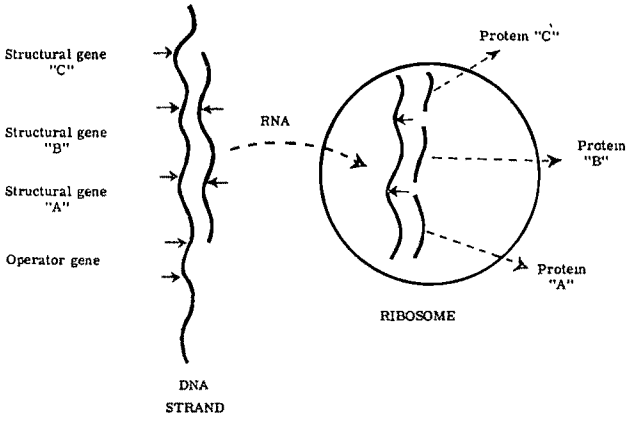

Fig. 1. A modified scheme for protein synthesis, necessitating equimolar production of each protein common to a single operon

A simple and unequivocal explanation thus becomes available for two aspects of the co-ordinate control of enzyme synthesis which are at present matters of conjecture. First, the remarkably constant ratio between the rates of synthesis of proteins within a group of this type becomes self-explanatory; secondly, the operator genes are no longer required to initiate RNA synthesis in structural genes which are geographically separated from them on the chromosome. With the techniques which are at present in use for the study of RNA synthesis, it should not be impossible to distinguish between the presently accepted model and that which is proposed in this communication.

Colour, Magnetic Resonance and Symmetry of the Cupric Site in Blue Protein

THE blue copper-proteins are characterized by very intense optical absorption near 600 mμ and unusually low cupric hyperfine splitting ($A_{\parallel}$) as observed by electron paramagnetic resonance. The nature of the copper-protein binding and the relationship between the colour and the electron paramagnetic resonance spectrum, while the subject of much investigation and speculation, have remained obscure[1–4]. However, almost all investigations have centred on ceruloplasmin and laccase, which contain eight and four atoms of copper per protein molecule, respectively, with only about half this number in the cupric state. It seemed, therefore, that these two proteins are not best suited for further investigation, particularly since it has been shown that blue proteins which contain only one cupric ion per molecule also have intense optical absorption near 600 mμ and small $A_{\parallel}$ values[5,6]. It was with the foregoing in mind that an investigation of the blue protein from *Pseudomonas aeruginosa* was undertaken. This protein has a broad absorption with a maximum at 625 mμ (molar extinction coefficient of approximately 2,000) and an $A_{\parallel}$ value of 60×10^{-4} cm^{-1}. The protein was isolated according to the method of Horio[7], with some modifications, and investigated in solution at room temperature and in frozen solution at −160° C by optical, electron paramagnetic resonance and optical rotatory dispersion methods.

The electron paramagnetic resonance spectrum of the native protein, *p*H 6·8, in frozen solution is in agreement with the published spectrum[5]. In the *p*H range 3–8 there is no change in the electron paramagnetic resonance spectrum, and there are only small fluctuations in the optical density at 625 mμ. In the *p*H range 8–12, the blue colour decreases in intensity very slowly, the rate of change of optical density increasing as the *p*H is raised. This change is reversible, the optical density being restored on decreasing the *p*H to a neutral value. In proportion to the decrease in optical density, the intensity of the electron paramagnetic resonance absorption decreases without any other change in the features of the spectrum (Fig. 1). Since the line width and shape of the absorption do not change (for *p*H less than 12), the amplitude is a measure of the intensity. The effect of urea at *p*H 6·8 was determined at several concentrations, and the resulting microwave versus optical absorptions are included in Fig. 1. The three points in the case of 7·7 M urea represent the time course of the process.

The severe reduction of electron paramagnetic resonance signal in alkaline solution and high urea suggests that the copper is reduced from cupric to cuprous under these conditions. To test this hypothesis, one drop of 10^{-2} M potassium ferricyanide in buffer at *p*H 9·6 was added to

1 ml. of protein solution at *p*H 9·6 which had lost 63 per cent of its optical density at 625 mμ. The optical density and the electron paramagnetic resonance spectrum were restored immediately to their original values, thus supporting the hypothesis. Potassium ferricyanide restores neither the colour nor the electron paramagnetic resonance spectrum of the protein in 7·7 molar urea, a fact which points to the stabilization of the cuprous state in the denatured protein.

The reduction of copper to the cuprous state is most probably effected by —SH groups, there being no other known reducing agents present. This reaction occurs either because the oxidation of sulphydryl groups is favoured at a high *p*H, or because of an increase in the redox potential of the cupric–cuprous couple. A change in the latter redox potential does not seem likely in alkaline solution (*p*H less than 12) in which the configuration of the protein is apparently not changed; whereas it is very likely on urea denaturation which changes the secondary structure. These considerations are supported by measurements of optical rotatory dispersion.

At neutral *p*H, this blue protein (in contrast to ceruloplasmin[8]) shows a marked Cotton effect in the visible region (Fig. 2). Therefore, the cupric ion is in an asymmetric environment in agreement with the views of Brill *et al.*[4]. As the *p*H is increased, this Cotton effect becomes weaker. It is absent in the protein denatured by 7·7 M urea. Also, in the *p*H range 8–10, the change in the optical rotation in the visible region is not accompanied by any change in the ultra-violet (this is consistent with the idea that the secondary structure of the protein is maintained); however, at 7·7 M urea the optical rotation in the near ultra-violet changes to larger negative values (indicating less helical structure).

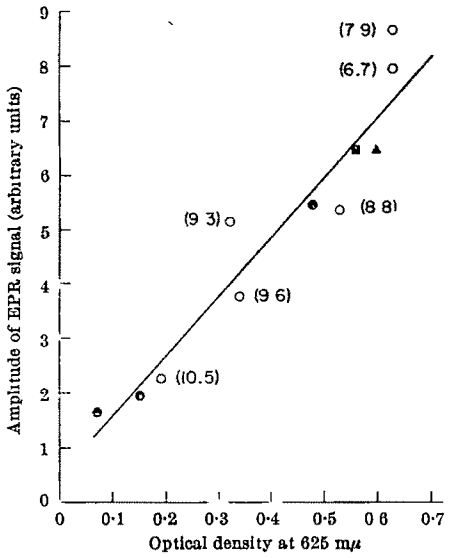

Fig. 1. Amplitude of electron paramagnetic resonance signal (arbitrary units) plotted against the optical density at 625 mμ. ○, No urea (the number next to each point is the *p*H of the solution); ■, 2 55 M urea; ▲, 5·1 M urea; ●, 7·7 M urea. All urea solutions were at *p*H 6·8 and the concentration of protein in all solutions was 3×10^{-4} M

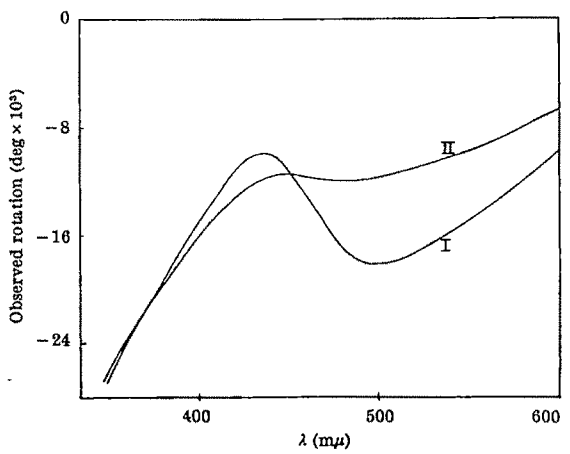

Fig. 2. Optical rotatory dispersion curves. (I) *p*H 7 9; (II) *p*H 9·6. The protein concentration was 3×10^{-4} M in both cases

Intracellular Distribution of the Different Forms of Lactic Dehydrogenase

There is, at present, considerable interest in the investigation of the properties and metabolic roles of the five molecular forms of lactic dehydrogenase (LDH). A preponderance of forms I and II was found in tissues (for example, heart) which function under relatively aerobic conditions, whereas a preponderance of forms IV and V was observed in relatively anaerobic tissues (muscle, liver)[1,2]. In a conference on lactic acids recently held in New York, however, it was brought out in discussion that the intracellular distribution of the different forms of LDH had not then been investigated[3].

In this communication we report data on the electrophoretic fractionation, on 'Cellogel' strips, stained with MTT tetrazolium, of the five molecular forms of LDH present in the nuclear, mitochondrial, microsomal fractions and in the supernatant of rat liver. Preparations of subcellular structural components were obtained in isotonic sucrose solution, fractionated on an 'International' refrigerated centrifuge and on a 'Spinco' *L* ultracentrifuge. The protein content of the single fractions was adjusted to a similar level. In total liver homogenate the principal band is the one which migrates most negatively (LDH_5), while only a very small band is present in the adjacent cathodic zone (LDH_4). These electrophoretic patterns are also present in the case of the nuclear and microsomal fractions and in the supernatant of the rat liver. Mitochondrial preparations always show an anodic band (corresponding to LDH_1, present in other organs). This band I is clearly greater than band IV (Fig. 1). The presence of LDH_1 could not be ascribed to erythrocyte contamination because the liver was previously carefully washed and because the erythrocytes should have been precipitated in the process of separation of the nuclei.

The fact that in the mitochondria, that is, in subcellular structures with a high aerobic metabolism, the first type of molecular form of LDH is clearly evident supports the view that this form is a catalyst geared for activity in an aerobic environment[1,2].

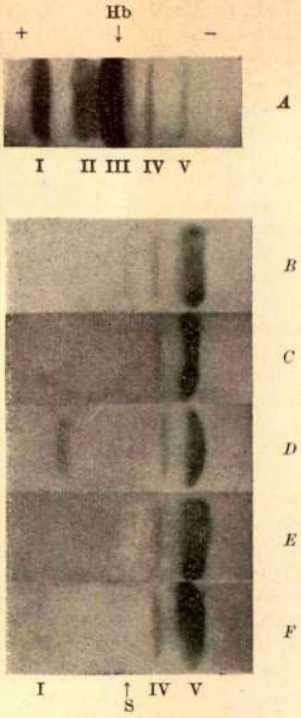

Fig. 1. Electrophoretic separation of molecular forms of LDH in rat liver. *B*, Total homogenate; *C*, nuclear fraction; *D*, mitochondrial fraction; *E*, microsomal fraction; *F*, supernatant. Cathodic bands predominate (LDH_4 and LDH_5), but in the case of the mitochondrial fraction an anodic band, corresponding to the LDH_1 of a haemolysate (*A*), is clearly evident

Triglyceride Accumulation in Liver

A number of experimental conditions, including various types of stress[1] and several treatments including administration of adrenocorticotrophic hormone (ACTH)[2], ethanol[3], carbon tetrachloride[4] and ethionine[5] induce an increase of the level of liver triglycerides.

The synthesis of triglycerides in rat liver depends largely on the availability of plasma free fatty acids (FFA) derived from lipolysis of triglycerides in adipose tissue[6]. The recent findings that drugs such as nicotinic acid[7], salicylic acid[8,9] and 3,5-dimethylpyrazole[10] can block FFA mobilization from adipose tissue suggested a possible new method for preventing or controlling the development of liver triglyceride accumulation in the aforementioned experimental conditions.

In a first experiment 180-g male Sprague–Dawley rats, fed *ad libitum* up to the beginning of test, were injected intraperitoneally with nicotinic acid (200 mg/kg), salicylic acid (300 mg/kg) or 3,5-dimethylpyrazole (15 mg/kg) and at the same time subcutaneously with ACTH ('Acthormone', Richter) at a dose of 200 I.U./kg.

4 h later the animals were killed by decapitation. Plasma FFA were analysed according to Trout *et al.*[11] and liver triglycerides were determined according to Van Handel and Zilversmit[12] after extraction with chloroform–methanol (2 : 1). The results reported in Table 1 show that the tested drugs reduce plasma FFA and prevent liver triglyceride accumulation.

Table 1. Effect of Drugs lowering Lipid Mobilization on Triglyceride Levels in Liver

Drug	ACTH (200 I.U./kg subcutaneously)	Plasma FFA μequiv./l. ± *S.E.*	Liver triglycerides mg/100 g ± *S.E.*
—	−	189 ± 12	554 ± 79
—	+	805 ± 26	1,912 ± 90
Nicotinic acid	+	650 ± 53	876 ± 68
—	+	906 ± 14	1,798 ± 94
Salicylic acid	+	547 ± 28	810 ± 72
—	+	883 ± 25	2,408 ± 232
3,5-Dimethylpyrazole	+	650 ± 95	600 ± 10

Drugs and ACTH were injected at the same time.
Rats fasted during the treatment—ACTH was given 4 h before killing.

In a second series of experiments, 3,5-dimethylpyrazole was given together with other treatments able to increase liver triglycerides. As shown in Table 2, 3,5-dimethylpyrazole was an effective antagonist in all the experimental conditions selected. Similar results not reported here in detail were also obtained with salicylic and nicotinic acids.

Table 2. Effect of 3,5-Dimethylpyrazole on Various Types of Triglyceride Accumulation in Liver

Treatment	3,5-dimethylpyrazole (15 mg/kg intraperitoneally)*	Plasma FFA μequiv./l. ± *S.E.*	Liver triglycerides mg/100 g ± *S.E.*
Exposure to cold†	−	600 ± 10	830 ± 63
Exposure to cold	+	559 ± 33	662 ± 30
Ethanol 2·1 ml./100 g per os	−	483 ± 30	1,340 ± 197
Ethanol 2·1 ml./100 g per os‡	+	346 ± 15	562 ± 79
Ethionine 150 mg/kg i.p.	−	916 ± 115	1,420 ± 160
Ethionine 150 mg/kg i.p.‡	+	653 ± 160	604 ± 50
Carbon tetrachloride 2·5 ml./kg per os	−	676 ± 10	1,427 ± 40
Carbon tetrachloride 2·5 ml./kg per os‡	+	473 ± 25	970 ± 80

* 3,5-dimethylpyrazole was given together with the treatment causing triglyceride accumulation.
† Rats were exposed to cold for 5 h and fasted during the treatment.
‡ Rats fasted 18 h before the beginning of the treatment. Ethanol was given 8 h before killing. Ethionine and carbon tetrachloride were given 5 h before killing.

In a last experiment, 3,5-dimethylpyrazole was injected intraperitoneally when accumulation of liver triglycerides was already induced either by ACTH or carbon tetrachloride. Table 3 shows the results obtained.

Table 3. Effect of 3,5-Dimethylpyrazole on Already Induced Accumulation of Liver Triglycerides

Treatment†	3,5-dimethylpyrazole (15 mg/kg intraperitoneally)*	Plasma FFA μequiv./l. ± *S.E.*	Liver triglycerides mg/100 g ± *S.E.*
ACTH 200 I.U./kg s.c.	−	685 ± 51	1,444 ± 195
ACTH 200 I.U./kg s.c.	+	191 ± 9	702 ± 106
Carbon tetrachloride 2·5 ml./kg per os‡	−	1,056 ± 114	1,831 ± 70
Carbon tetrachloride 2·5 ml./kg per os‡	+	414 ± 43	1,899 ± 142

* 3,5-dimethylpyrazole was given 30 min before killing.
† ACTH and carbon tetrachloride were given 5 h before killing. Rats fasted during the treatment.
‡ Rats were fasted the night before the experiment.

It is evident that after 30 min from the administration of 3,5-dimethylpyrazole there is a considerable decrease of liver triglycerides in the case of accumulation induced by ACTH but not in the case of carbon tetrachloride. This difference could be explained on the basis of observation that carbon tetrachloride[13], as opposed to ACTH, blocks the transfer of triglycerides from liver to plasma. The block of liver triglyceride synthesis due to the decreased availability of plasma FFA therefore results in a rapid decrease of liver triglycerides only when, as after ACTH treatment, the transfer of triglycerides from liver to plasma is still occurring.

The data here reported show that drugs preventing release of FFA from adipose tissue are able to prevent and, in some cases, to lower liver triglyceride accumulation even if the cause of such an increase of liver triglycerides is not an increased lipid mobilization.

These results may have a more general implication and might explain by means of a common mechanism why several conditions such as spinal transection and adrenalectomy[14] and a number of drugs such as nucleotides[15] and adrenolytic agents[14] prevent accumulation of triglycerides.

It is suggested that drugs and procedure preventing fatty liver should be tested also for their capacity to lower plasma FFA.

We thank Dr. G. C. Gerritsen (Upjohn Co.) for a sample of 3,5-dimethylpyrazole and Miss A. M. Codegoni for technical help.

Sex-associated Protein in Liver Tissue of the Rat

A protein component has been described[1-3] which appeared to be present in liver tissue of the male rat but absent from that of the female. The response of this substance to varied endocrine manipulation suggests that its presence or absence is dependent on the sex hormones. testosterone potentiating and oestradiol inhibiting the formation of the protein. Recently[4], this work has been confirmed and extended to show that progesterone also has an effect causing the appearance of the protein in the female and an increase in the amount found in the castrated male.

Investigations on this unusual protein have continued. The protein has been purified to the extent that a highly specific antiserum has been prepared. The reagent produces a single precipitin band when diffused in agar against the 105,000*g* supernatant[5] from liver homogenates. The sensitivity of the agar-diffusion techniques is such that it has become possible to detect the protein in livers of normal female rats. The concentration ratio is about thirty-two times less in the female than that in the male. Both single[6] and double[7] diffusion quantitative agar techniques give good agreement with this figure which, nevertheless, lacks precision because of its logarithmic nature. Stability problems associated with preparing the highly purified protein have prevented the accumulation of sufficient material to use more sophisticated quantitative methods and, thereby, to arrive at the absolute amounts present in tissue.

It would be of considerable interest to know if the sex-associated protein exists as a circulating entity in the blood. Thus far, it has not been detected there either chromatographically or by the much more sensitive immunochemical techniques.

It would seem that the adrenal glands are not directly concerned with this sex-associated phenomenon. The adrenalectomized female still responds to testosterone treatment, although rather poorly compared with the intact animal. Adrenalectomy seems to cause no significant change in the amount found in the male. The adrenalectomized male responds similarly to the intact male when treated with oestradiol.

Animals have been treated with oestradiol and testosterone simultaneously with the same dose schedule and proprietary preparations used previously[3]. Interestingly, the sex-associated component disappeared rapidly in the male similarly to that seen when oestradiol was given alone. At about 20 days after treatment, however, the longer lasting testosterone repository apparently caused a rapid reappearance of the component. A similar phenomenon occurred in the female, in which case the sex-associated protein began to be present in substantial amounts after about 20 days. These observations strengthen the argument for a direct-acting antagonism between the hormones and for a reciprocal dose relationship.

The physiological significance of the sex-associated protein is still unknown. Intuitively, it may be assumed to have considerable importance as judged by the comparatively large amounts found in adult male liver[3,4]. Experimentally, the protein may be of considerable value in investigating physiological processes in the liver. With the elimination of a necessary adrenal involvement, the evidence favours that of a direct response to sex hormones. In itself this provides a means for studying a highly specific response to hormone action in addition to studying the consequences of the action. Sensitive immunochemical techniques will be most valuable in further investigations on this sex-associated phenomenon.

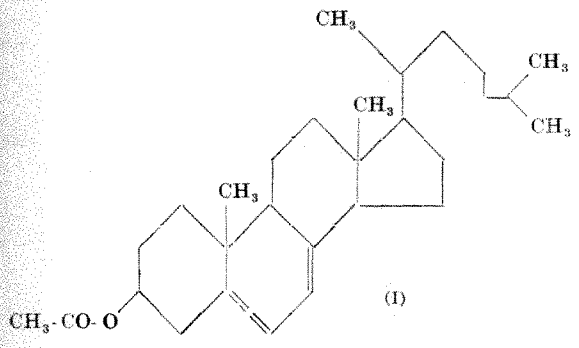
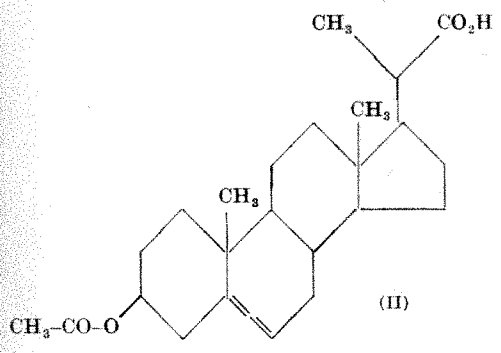
Carcinogenic Activity *in situ* of Further Steroid Compounds



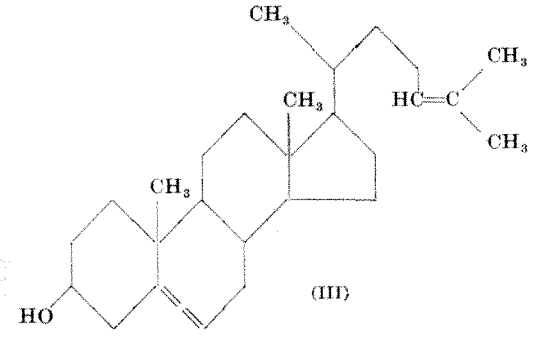
There is more and more evidence coming from several research groups that a number of steroid molecules with no hormonal competence nevertheless possess carcinogenic properties. Ghiron[1], and later Cook *et al.*[2], obtained sarcomas with deoxycholic acid by subcutaneous injection in mice; cholesterol itself has been shown by Hieger[3] to produce a 12 per cent incidence of sarcomas, as against 0·8 per cent in control mice injected with the solvent alone. More recently, we recorded the activity of apocholic acid, a dehydration product of cholic acid; it gave sarcomas in 4 out of 42 mice, as compared with 0 per cent in 350 mice injected with the solvent alone[4]. Tumours have also been recorded by Bryson and Bischoff[5] in Marsh mice given testicular injections of cholesterol α-oxide. We wish now to report on the definite sarcomagenic activity of two further steroid molecules, one with a biochemical function, 7-dehydrocholesterol [in the form of its acetate (I)], the precursor of vitamin D_3, and the other, 3β-acetoxy-bisnor-Δ^5-cholenic acid (II), a product of the artificial oxidative degradation of several sterols and bile acids[6].

Sixty 3- to 5-month-old mice (28♀ and 32♂) of strain XVII *nc/Z* (Radium Institute) received subcutaneously, in the right flank, ten injections (with a 10-day interval between each) of 0·5 mg of 7-dehydrocholesterol acetate dissolved in 0·2 c.c. sterile neutralized olive oil. The first tumour was detected at the site of injection, 210 days after the first injection, in one male mouse out of the 52 surviving animals. Two other tumours developed in 392 and 482 days, in a male and female mouse respectively. In all



three cases the tumour was a typical fibrosarcoma. Forty-one animals survived for longer than 500 days.

A second group of 60 mice (28♀ and 32♂), of similar age and strain as for the first group, was given 10 injections of 0·5 mg of 3β-acetoxy-*bisnor*-Δ^5-cholenic acid, in the same experimental conditions. After 526 days an *in situ* sarcoma developed in a female mouse; by that time, 38 animals still survived. A second sarcoma was observed in a male mouse after 609 days.



In a third group comprising 71 mice (23♀ and 48♂), treated in the same conditions with 24-dehydrocholesterol (desmosterol) (III) (0·5 mg; 10 injections), no tumour was obtained; 36 of the animals survived for over 650 days.

(I)

(II)

(III)

Although the yields in tumours (5 per cent for compound (I) and 3·3 per cent for compound (II)) were low, evidence that 7-dehydrocholesterol acetate and 3β-acetoxy-*bisnor*-Δ^5-cholenic acid act, in our strain of mice, as true carcinogens rests on the facts: (*a*) that spontaneous sarcomas of the soft parts have never occurred in that strain; (*b*) that in our laboratory, subcutaneous injections of the solvent alone (that is, neutralized olive oil) have always failed to produce any sarcomas *in situ*, as observed in more than 530 animals; and (*c*), that most of the steroid molecules tested by us previously, as well as 24-dehydrocholesterol reported here, are completely inactive in our experimental conditions.

Both 7-dehydrocholesterol and 24-dehydrocholesterol are minor constituents of the tissues of higher animals and man; the weak but definite sarcomagenic activity of 7-dehydrocholesterol is a further point in favour of the existence of endogenous carcinogens in normal tissues. As for 3β-acetoxy-*bisnor*-Δ^5-cholenic acid, its close chemical relation to the bile acids suggests that further compounds of this type should be tested for carcinogenic activity.

An Investigation of Plant Seeds for Adenosine Deaminase

Adenosine deaminase (adenosine aminohydrolase, *EC*3.5.4.4) of plant origin was first reported in a commercial sample of malt diastase[1]. Later, its presence in extracts from barley rootlets was claimed[2]. Another study, however, failed to detect deaminase activity in any of a number of plants examined[3]. On the other hand, most animal cells[4] and many micro-organisms[5] are known to contain enzymes capable of deaminating adenosine.

In this investigation, the seeds of twenty plants were tested for deaminase activity, with particular attention being given to barley.

The seeds were ground in a sterilized coffee mill and 20 per cent aqueous extracts prepared from the powder. Enzyme activity was measured by determining ammonia release from an incubation mixture composed of 2 ml. 0·5 per cent adenosine in 0·1 M phosphate buffer *p*H 7·0 and 1 ml. of seed extract[6]. Substrate and seed-extract controls were always included. Activity was recorded in micro units (μu.).

Barley seeds, both fresh and germinated, had activity after 15 h incubation, but no activity could be detected with short incubation times of 1–3 h. Germination always resulted in increased activity but there were considerable fluctuations in the activity of different extracts of the same seed sample. Addition of 0·1 ml. saturated benzoic acid caused 60 per cent reduction, while 0·1 ml. saturated thymol completely suppressed activity. Filtration of the extract through a bacterial membrane filter of average pore size 200 mμ resulted in a 56 per cent reduction in activity, while a second filtration produced a further reduction to 29 per cent of the original.

A bacteriological examination kindly carried out by Prof. O'Mullane, Department of Dairy Bacteriology and Microbiology, University College, Cork, showed that the unfiltered seed extract was heavily contaminated with micro-organisms. Although there was diminution in their number after filtration, the second ultra-filtrate was still appreciably contaminated.

The deaminase in an extract of calf mucosa showed no reduction of activity with these treatments. It is evident, therefore, that plant and animal cell extracts differ in the nature of their deaminase activity.

From the foregoing findings it appeared that developing micro-organisms might be the cause of activity in barley seed extracts. To test this, the activity/time relationship in a plant and animal extract was compared. Activity in each case was measured at 3-h intervals during a 24-h incubation period at 37° C.

Fig. 1 shows that the mammalian extract gave a steady release of ammonia resulting in almost identical activity

values throughout the 24 h. The barley extract, in contrast, showed no activity at 3 h, only slight activity after 6 h, followed by a rapid increase, terminating in a plateau of almost constant activity after 15 h. The graph (Fig. 1) shows a striking similarity to a typical bacterial growth cycle with a lag phase, followed by a logarithmic growth phase and terminating in a stationary phase. It demonstrates that enzyme is being formed during the incubation. As cell-free extracts were used, enzyme formation by the plant was ruled out, so that the appearance of activity must be due to micro-organisms developing during the incubation. The fact that there was no ammonia release at 3 h means that deaminase activity, if present, in the barley is below 1 μU. or less than 1/10 of that found in blood plasma, the animal tissue with lowest activity.

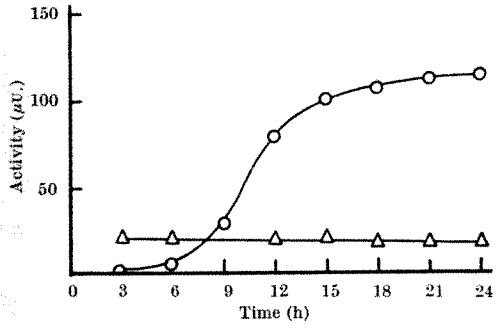

Fig. 1. Comparison of adenosine deaminase activity in extracts of barley seed and of calf mucosa. ○, Barley seed; Δ, calf mucosa. Assays were performed in 0·33 per cent adenosine in 0·1 M phosphate buffer at *p*H 7·0 at 37° C. Results are expressed as specific activity. Values for the calf mucosa are multiplied by 10^{-3}

Two samples of dried barley rootlets (combings) were assayed in the same way. One extract showed no activity throughout the 24-h incubation. The second extract had no activity at 6 h, after which low activity appeared up to 18 h, followed by a steep increase at 21 and 24 h.

Fresh barley roots were grown in water culture. An extract of the roots was prepared by homogenization. No activity was evident at 3 h, but after 9 h activity appeared and increased steeply until the termination of the experiment. These results, similar to those with seeds, provide no evidence for the presence of adenosine deaminase in either dried or fresh barley roots.

The following seeds were assayed for adenosine deaminase activity: Family (1) Gramineae: wheat, oats, barley; (2) Cypraceae: sedges; (3) Junaceae: rushes; (4) Liliceae: onions; (5) Leguminosae: peas and beans; (6) Compositae: lettuce; (7) Umbelliferae: celery; (8) Ranunculaceae: buttercups; (9) Cucurbitaceae: vegetable marrow; (10) Cruciferae: white turnips; (11) Papaveraceae: poppy; (12) Ericaceae: heather; (13) Gerianiaceae: geranium; (14) Malvaceae: mallow; (15) Chenopodiaceae: beet; (16) Solanaceae: tobacco; (17) Polygonaceae: buck wheat.

Extracts were prepared as previously described, but incubations were conducted at a temperature of 25° C.

A selection of the results is given in Fig. 2 which includes, for comparison, a similarly treated extract of calf mucosa. With only two exceptions, the seed extracts gave either no ammonia release or a very slight amount after 12 h.

In all cases, except those seeds giving negligible ammonia release, the graph of ammonia formation with time was curved in contrast to the animal extract, which gave a straight line. Mallow and celery gave some ammonia release at 3 h, but the course of the subsequent release indicates that here, too, micro-organisms were responsible for the deaminase activity.

These results call into question the claims that adenosine deaminase is present in barley. Its presence in malt diastase[1] cannot be taken as proof of its occurrence in barley seed, because malt diastase is prepared from

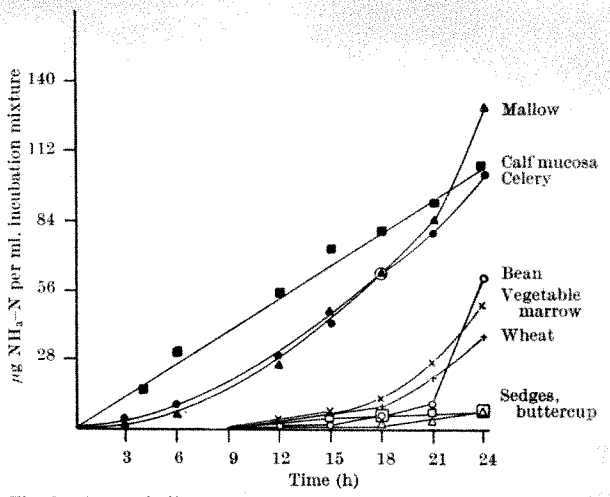

Fig. 2. Ammonia liberation from adenosine by seed extracts. Assay conditions were identical to those used in Fig. 1, except that the incubation temperature was reduced to 25° C. The calf mucosa was diluted 1 : 350,000

germinated barley and, therefore, likely to be extensively contaminated with micro-organisms. Doubt must also be expressed about its reported presence in barley rootlets in view of the long incubation times used and the semi-quantitative nature of the assay method used[2].

Unequivocal proof for the existence of adenosine deaminase in any type of higher plant is still lacking, and the conclusion that adenosine deaminases are of much less widespread occurrence in higher plants than in other forms of living matter seems inescapable.

We thank the Medical Research Council of Ireland; the European Research Office, U.S. Department of the Army, for financial support; and the Department of Education for a training grant to one of us (V. J. H.).

Effect of Aeration on the Consumption of Ethanol by the Isolated Perfused Rat Liver

In a particular series of experiments designed to determine ethanol consumption by the isolated perfused rat liver it was observed that consumption patterns differed from that obtained in the intact animal. The following experiments were conducted to show how normal consumption patterns can be obtained by changing the aeration media of the blood from the usual 95 per cent oxygen, 5 per cent carbon dioxide, to a mixture containing 18 per cent oxygen, 5 per cent carbon dioxide, and 77 per cent nitrogen.

The liver perfusion apparatus and details of the operation have already been described[1,2]. Young male albino rats weighing between 200 and 300 g were used in all the experiments. The perfusate consisted of freshly drawn blood from rats, and to this was added 24 mg/100 ml. of heparin. The volume of the perfusate was maintained at 90–100 ml. throughout the 4-h experiment. The temperature of the system was maintained at 38° C and the aeration medium used was either 95 per cent oxygen, 5 per cent carbon dioxide or 18 per cent oxygen, 5 per cent carbon dioxide and 77 per cent nitrogen. The rate of loss

of ethanol by evaporation in the aerating 'lung' was determined experimentally.

To determine the ethanol concentration samples were removed from the perfusate at 10-min intervals during the first 90 min of the experiment, and thereafter at 15-min intervals, and immediately transferred to a chilled, air-tight vial. The ethanol vapour in the volume above this aliquot was allowed to equilibrate at 37° C and was afterwards analysed utilizing a Loenco gas chromatograph, model 70, equipped with a hydrogen flame ionization detector. Adequate precautions were taken to prevent any loss by condensation when transferring this measured gas sample to the system for analysis. The operating conditions were as follows: a 6 ft. × 0·125 in. stainless steel column packed with 20 per cent 'Carbowax 20 *M*', on HMSD 'Chromosorb *W*' 60/80 mesh, was maintained at 78° C, and utilized helium as the carrier gas, with a flow rate of 30 ml./min. The retention time of ethanol was 2·25 min. The ethanol concentrations were calculated by measuring peak area and comparing these areas to those of suitable ethanol standards treated in the same manner as the unknowns.

The data illustrated in Fig. 1 show the effect of different aerating media. Eight experiments were conducted using 95 per cent oxygen, 5 per cent carbon dioxide and an initial concentration of 240 mg of ethanol per 100 ml. of perfusate. Concentrations of ethanol in the perfusate are plotted against time. It is apparent that the concentrations vary exponentially with time for these particular experiments. This is shown more clearly in Fig. 2, in which the logarithm of the concentration is plotted against time. In this plot the data appear as two distinct straight-line segments of differing slopes with a distinct break at an ethanol concentration of approximately 40 mg/100 ml. of perfusate. Such a dependence indicates that the consumption of ethanol depends primarily on the concentration of ethanol in the blood and that a distinct change in the mechanism of consumption occurs at the break point. The time taken for the concentration to fall to one-half of its original value ($T\frac{1}{2}$) is a recognized measure of the rate of consumption for this type of curve. The $T\frac{1}{2}$ for the upper segment of the curve was 45 min, and for the lower segment was 20 min. In these calculations a small correction has been made for the loss of ethanol by evaporation during the aeration process.

Five experiments were conducted using 18 per cent oxygen, 5 per cent carbon dioxide, 77 per cent nitrogen gas mixture; quite different results are obtained, as indicated by the remaining data in Fig. 1. A straight line can be drawn through these points, indicating that ethanol is now disappearing at a constant rate which is

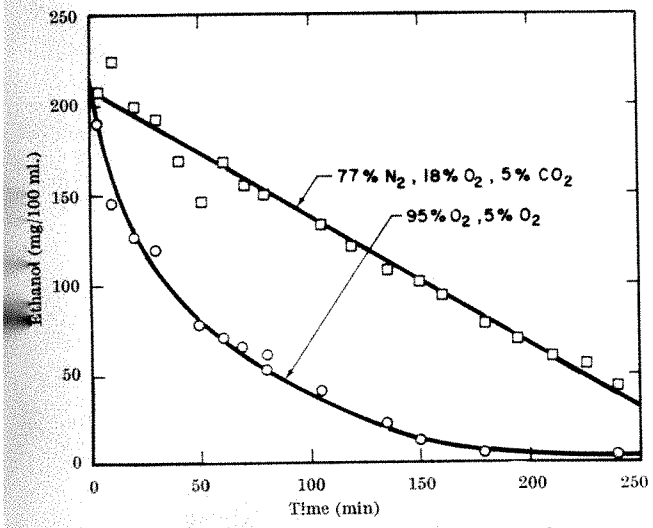

Fig. 1. A linear plot of ethanol concentration in the perfusate

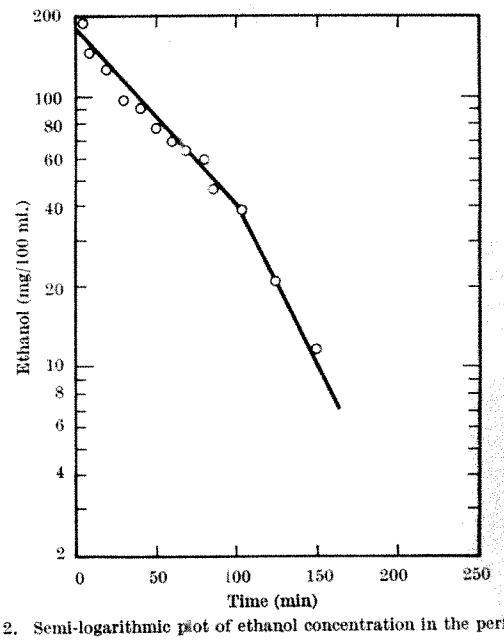

Fig. 2. Semi-logarithmic plot of ethanol concentration in the perfusate

independent of the ethanol concentration. When corrected for evaporation losses, the ethanol consumption indicated by these data is 36 mg/100 ml. per 10 g of liver per hour, and is within the range published for the intact rat[3–5]. In these experiments there is no doubt regarding the differences in magnitude and shape of the curves involved. The use of 95 per cent oxygen, 5 per cent carbon dioxide atmosphere results in a non-physiological mode of consumption.

At this stage of the investigation, no clear answer can be given as to the mechanism involved in the consumption of ethanol for these different aeration media. However, some inferences seem reasonable. Bauer *et al.*[6] have indicated that there is a fourfold increase in the consumption of oxygen by the isolated perfused rat liver when the oxygen in the aerating media is changed from 18 per cent to 95 per cent. It seems reasonable to postulate that the rate-limiting step in the metabolism of ethanol by the liver may be controlled by the availability of oxygen. Since Theorell[7] and his group have indicated that the rate of oxidation of reduced nicotinamide-adenine dinucleotide ($NADH_2$) formed when ethanol is oxidized to acetaldehyde is the rate-limiting step, this assumption seems reasonable. It is evident that further information on the levels of $NADH_2$ and NAD in these perfused livers would greatly aid in the understanding of the mechanisms involved. A pertinent feature of these experiments is the demonstration that an isolated organ in an artificial system can utilize ethanol at rates similar to that found in the intact animal.

In this investigation, these 'normal' rates were only observed if the oxygen partial pressure of aeration media approached that of air. These findings suggest that caution must be exercised in the interpretation of data arising from investigations utilizing media of abnormally high oxygen partial pressures.

I thank Mrs. B. Ahlstrom for her help in this work.

PHYSIOLOGY

Sciatic Nerve Activity evoked by Sensory-motor Cortex Stimulation during Paradoxical Sleep

The cortico-spinal system undergoes consistent modifications during the desynchronized phase of sleep. The integrated pyramidal activity rises to a level even higher than that reached in wakefulness[1]; the pyramidal tract neurones change their temporal pattern of discharge[2]; the integrated pyramidal activity increases synchronously with rapid eye movements and myoclonic twitches[3]; and the sciatic nerve responses to liminar pyramidal stimulation are abolished[4].

The aim of the present investigation was to study the behaviour of sciatic nerve responses to sensory-motor cortex stimulation during sleep and wakefulness, in order to obtain further information on the function of the cortico-spinal system during these physiological phases.

The experiments were performed on unrestrained, unanaesthetized cats with chronic implanted electrodes. Bipolar stimulating electrodes were applied subdurally on the surface of the sensory-motor cortex of one side. Bipolar electrodes left in place around the sciatic nerve of the opposite side could record the spontaneous and evoked activity of a large population of lumbo-sacral motoneurones. The sensory-motor cortex was stimulated with bursts of from two to five stimuli at 300/sec, 0·05–0·5 msec, 1–3 V delivered every 1–2 sec. The spontaneous and evoked activity in the sciatic nerve was recorded on an 'Ampex' tape-recorder during wakefulness, synchronized sleep and desynchronized sleep, averaged on a *CAT* 400 'Mnemotron' and then photographed on an oscilloscope. The electroencephalogram (from frontal areas), the electromyogram (from nuchal muscles) and the oculogram indicated the stages of wakefulness and sleep which occurred during the experiments.

During wakefulness without apparent movements of the animal, a spontaneous activity was present in the sciatic nerve. A train of from two to five stimuli delivered to the sensory-motor cortex evoked a complex response on the neurogram with a latency of 12–18 msec from the first stimulus. Synchronous with the electrical potentials, which fluctuated in amplitude, a slight flexion of the hindleg of the same side was generally observed. Fig. 1*A* shows an average of fifty responses during wakefulness in which three main deflexions are seen. During synchronous sleep the evoked activity in the sciatic nerve was usually slightly reduced in amplitude, although did not change in its latency and pattern (Fig. 1*B*). It can be seen that the first and second deflexions are reduced in amplitude as compared with wakefulness. When the animal went into an episode of paradoxical sleep (with desynchronized EEG, flattening of nuchal muscles and rapid eye movements, REM) the evoked activity was usually tonically reduced in amplitude with phasic marked increase generally synchronous with the bursts of REM. The averaged values were often higher than those observed during wakefulness (Fig. 1*C*), the increase being proportional to the amount of REM present during the paradoxical sleep episode. It can be seen that the latency of the discharges does not change, while the increase in amplitude affects particularly the second and third deflexions of the neurogram. Both the second and the third deflexions also appear to be slightly shorter in duration than those seen in Fig. 1 *A* and *B*. The results indicate that the excitability of the corticospinal system is tonically depressed during synchronized and desynchronized sleep, whereas it increases during wakefulness and REM periods of desynchronized sleep. Since the sciatic nerve activity evoked by liminar pyramidal stimulation is abolished during paradoxical sleep[4] the phasic enhancement of activity evoked by sensory-motor cortex stimulation during this phase may be due to an increase of cortical excitability.

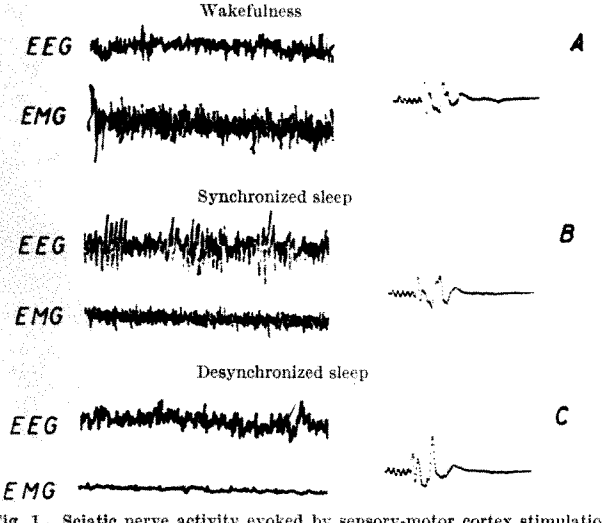

Fig. 1. Sciatic nerve activity evoked by sensory-motor cortex stimulation during wakefulness, synchronized and desynchronized sleep. Chronic unrestrained, unanaesthetized animal with frontal EEG and nuchal EMG. *A*, *B* and *C*: fifty averaged sciatic nerve responses evoked by stimulation of the contralateral sensory-motor cortex with bursts of 5 impulses at 300/sec, 0·07 msec, 3 V during wakefulness (*A*), synchronized sleep (*B*) and desynchronized sleep (*C*). Sweep duration 125 msec

Electrocardiograms of Lambs in Selenium Deficiency

Studies have been made of lambs taken from their dams at 4 weeks of age and weaned, by stages, on to a selenium-deficient diet of the type used by Schwarz[1] for the development of dietary hepatic necrosis in rats. Lambs on this diet develop muscular dystrophy, the lesions appearing in both the cardiac and skeletal musculature; the livers do not become necrotic as they do in the rat. Control lambs fed the same diet, supplemented with an oral drench of 10 mg of sodium selenite per week, do not develop muscular dystrophy.

Electrocardiography on these lambs reveals the development of a characteristic abnormality. As the disease progresses the *T*-wave increases in amplitude until it finally dominates the record; at this stage the elevated *S–T* segment is typical of the pattern of myocardial infarction in man (Figs. 1 and 2). As the abnormal electrocardiograph develops progressively over a period of

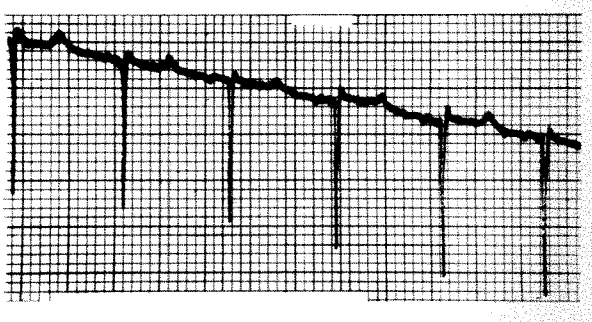

Fig. 1. Electrocardiogram of a lamb maintained for a few weeks on a selenium-deficient diet. At this stage no abnormality has developed in the electrocardiogram pattern

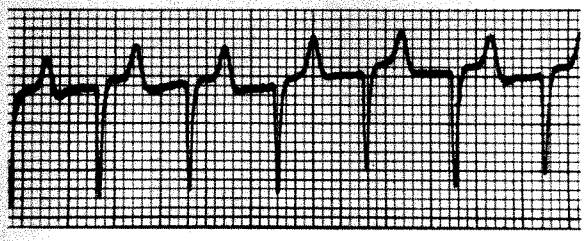

Fig. 2. Electrocardiogram of the same lamb as is shown in Fig. 1. However, the lamb is at this point clinically dystrophic and the electrocardiogram pattern shows the typical elevated *S–T* segment of myocardial infarction

2–3 weeks before the deficiency syndrome leads to death, it is possible to monitor the course of the deficiency symptoms.

It remains to be seen whether the same type of electrocardiogram change occurs in 'white muscle disease', a malady of sheep that are grazed in particular areas and which responds to selenium therapy[2].

I have already reported[3] that similar changes occur in selenium-deficient rats.

Glucose Metabolism of Central Nervous Tissues in Rats with Experimental Allergic Encephalomyelitis

THE incorporation of carbon from glucose-^{14}C and acetate-1-^{14}C into lipids of the central nervous system has been shown to be greater than normal in rats with experimental allergic encephalomyelitis (EAE)[1,2]. In order to explore further the metabolism of tissues from animals with this demyelinative condition, glucose uptake, carbon dioxide production and lactate accumulation *in vitro* were measured in brain stem and spinal cord slices from rats in the acute paralytic stage of experimental allergic encephalomyelitis. As controls, similar slices were investigated from both normal animals and those injected only with Freund's adjuvant.

Fourteen Wistar rats, 6 weeks old, were injected in the hind foot pads with 0·5 ml. Freund's adjuvant (obtained from Difco) containing 85 mg homogenized guinea-pig spinal cord. The controls were litter-mates matched in regard to weight and sex, fourteen of which were injected with 0·5 ml. Freund's adjuvant; the remaining fourteen served as normal controls. When paralysis of the hind feet became apparent in the group receiving nervous tissue homogenate (12–15 days after injection), the animals were killed by cervical fracture, the brain stem and spinal cord removed, sliced and incubated in Warburg flasks containing 3 ml. Krebs–Ringer phosphate with 3 μc. uniformly labelled glucose-^{14}C in 3 mg glucose. Potassium hydroxide was present in the centre well for carbon dioxide absorption. The flasks were incubated under oxygen in a Dubnoff Metabolic Shaker at 37° for 1 h. At the end of this time 0·2 ml. perchloric acid was tipped in from the side arm and the flasks incubated 30 min longer. The potassium hydroxide was removed from the centre well and the absorbed carbonate precipitated by the addition of barium acetate. The barium carbonate was plated and counted in a gas-flow Geiger–Müller counter using an end window. The medium and slices were removed from the flask, centrifuged, and the medium decanted. Subsequent washings of the slices were added to the medium. Aliquots of the medium plus washings were used for lactic acid measurements according to Barker and Summerson[3] and for glucose determinations according to the carbohydrate method described by Svennerholm[4].

Table 1 shows glucose uptake in the EAE brain stem and spinal cord to be very close to the normal. A slightly higher uptake of glucose was shown in the Freund's adjuvant-injected controls, however, and this was significantly different from the normal in the spinal cord ($P < 0·01$), but not in the brain stem. The lactic acid level of the incubation medium was markedly higher than the normal in both the brain stem and spinal cord of the EAE animal ($P < 0·01$). These higher levels are significant also when compared with the Freund's adjuvant-injected control. No significant difference was seen between the Freund's adjuvant control and the normal control.

The level of specific activity in the carbon dioxide produced by the brain stem was not significantly lower than the normal, but was significantly different ($P < 0·01$) from the Freund's adjuvant controls. The spinal cord carbon dioxide specific activity was, however, significantly less ($P < 0·01$) than both groups of controls.

Two explanations for the lowered specific activity of the carbon dioxide are possible. A lowered production of carbon dioxide by the slices seems most plausible when the high lactic acid levels are taken into account. It is possible also that other non-labelled constituents are being oxidized in the EAE animal, thus resulting in a decreased specific activity of the carbon dioxide.

If the former explanation is considered, the present results would indicate that an abnormal carbohydrate metabolism is present in nervous tissue from the EAE animal. This abnormality is not seen in glucose uptake, but seems to exist somewhere between the lactic acid and carbon dioxide stages of carbohydrate metabolism or the tricarboxylic acid cycle. The enzymes required in this pathway are known to be located in the mitochondria. Other preliminary evidence[5] would indicate that the mitochondria are involved in the increased rate of lipid synthesis previously described in the EAE animal[1,2]. In electron microscope pictures Roizin has shown mitochondria of the central nervous system of the EAE guinea-pig which are abnormal in appearance[6].

At present it is not known whether these abnormal metabolic relationships may be related to the demyelinative condition. It is possible that the paralysed nerves may utilize glucose differently, or that paralysis may

PHARMACOLOGY

Possible Neurotoxicity of Diisopropyl Phosphorofluoridate in Guinea-pigs

Neurotoxicity (demyelination and axon degeneration) caused by various organophosphorus compounds is said to occur only in certain species[1,2]. According to Davies[1], guinea-pigs show no delayed paralytic effect after treatment with one of the neurotoxic compounds. We have found that guinea-pigs treated with diisopropyl phosphorofluoridate (DFP) show delayed paralytic effects. This report outlines the gross signs of neurological damage observed.

Ten male guinea-pigs each weighing about 800 g were treated subcutaneously with 1 mg/kg of DFP per day for 4 days. This amount of DFP was not sufficient to cause convulsions. However, the animals were highly excitable for the 4 days and subsequent few days.

The development of symptoms generally occurred as shown in Table 1. As might be expected, there are overlaps in the times at which the symptoms were first noticed.

The peculiar gait of the two guinea-pigs (walking with raised quarters) appeared to be due to spasticity of the hind limbs. Otherwise, the paralysis was flaccid. The walking on the hocks indicated that the lower muscles of the hind limb were initially weakened and that afterwards the muscles of the entire limb became paralysed.

Table 1. Development of Symptoms in DFP-treated Guinea-pigs

Days	Symptoms
1–4	Injections of 1 mg/kg daily; excitable
5–7	Excitable
10–14	Walked on hocks of hind legs. Sores on hocks. Pronounced thumping sound when walking, heavy-footed
15–20	Ataxic—hind quarters wobbled when walking
20–35	In two animals, ataxia became worse until hind limbs were completely paralysed. These animals scrambled with fore limbs when trying to move, but the hind quarters were completely paralysed. These two died, one at 28 days, the other at 35 days. Both showed large loss in body-weight. Two animals walked with hind quarters higher than the front quarters
35–50	Started to recover
75 days	All seven survivors appeared normal except one, which still had a weak right hind limb. One was killed for histological examination

This description is a composite picture and not all animals showed the severest signs. The least affected showed symptoms no worse than the sores on hocks and heavy-footedness (two animals).

We believe that the neurological signs shown by the guinea-pigs treated with DFP indicate that neurotoxicity is brought on by organophosphorus anticholinesterases in this species. It must be emphasized that the neurological lesions which one would have expected to accompany the symptoms described were not observed.

HAEMATOLOGY

Synthesis of α_2-AP (Acute Phase) Globulin of Rat Serum by the Liver

The appearance of a new protein in rat serum in a wide variety of pathological and physiological states has been reported by several investigators in recent years[1,2]. The protein which we have designated α_2-AP (acute phase) globulin[1] has also been referred to as slow α_2-globulin (SA_2G) (ref. 1), abnormal serum component[1], reproduction-associated protein[1], and α_2-glycoprotein (α_2-GP) (ref. 2). The presence of the protein in serum has been detected by immunological procedures[1,2] and by filter paper-[1] and starch-gel-electrophoretic analyses[1]. The present communication reports the demonstration of the synthesis of α_2-AP globulin by the liver during the acute phase of an inflammatory response.

An anaesthetized, adult, male rat of Sprague–Dawley origin, weighing about 400 g, was injected with 1·0 ml. of a sterile solution of spirits of turpentine, N.F., in corn oil (v/v) as previously described[3]. Twenty-four hours later the rat was exsanguinated by cardiac puncture under ether anaesthesia and the liver removed aseptically. Tissue culture and radioimmunoelectrophoretic techniques were the same as those described in an earlier publication[3], with the exceptions that the film was exposed for 3 weeks, and an antiserum specific for α_2-AP globulin was used. Antiserum was prepared by immunizing rabbits with pooled sera from 'turpentine-stimulated' rats. The antiserum specific for α_2-AP globulin was obtained by absorbing the original with normal rat serum[1].

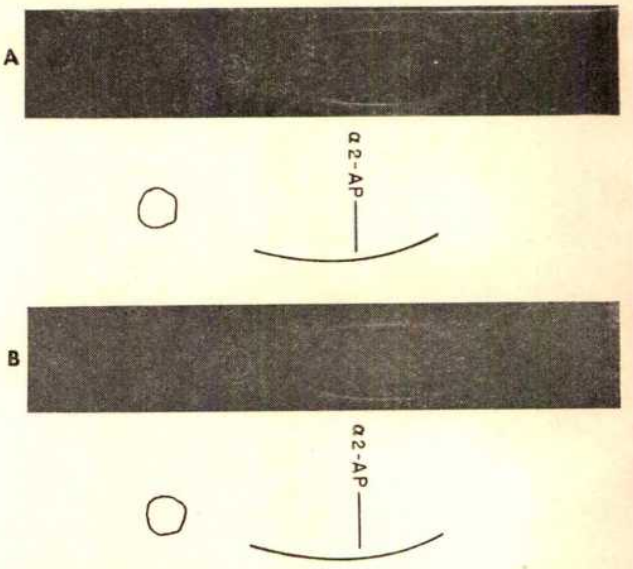

Fig. 1. *A*, Photograph and schematic representation of immunoelectrophoretic analysis of mixtures of tissue culture fluid and carrier serum proteins from donor rat using monospecific antiserum. *B*, Photograph and schematic depiction of autoradiograph of same slide

Fig. 1*A* shows a photograph of the immunoelectrophoretic analysis of the concentrated tissue culture fluid with carrier proteins using the monospecific antiserum. Fig. 1*B* is the autoradiograph of the same slide. Hepatic synthesis of α_2-AP globulin was unequivocally demonstrated by the radioactive labelling of the specific precipitin arc.

When the unabsorbed antiserum was used to develop the immunoelectrophoretic patterns, incorporation of the radioactive label into twelve other proteins was observed, as noted in a previous report[3].

New Variant of Haemoglobin G, Haemoglobin G_{Paris}

Since the first haemoglobin G was described in 1954 (ref. 1), several varieties have been observed. Structural analysis has shown that the electrophoretic mobility could be due to various amino-acid substitutions in the α- as well as in the β-chain. The only similarity between all these haemoglobins is that the net charge differs from that of normal haemoglobin and that they migrate close to haemoglobin S, but a little faster in alkaline buffer.

This communication describes a new variety of haemoglobin G, which we propose to call haemoglobin G_{Paris}. Different techniques were used: starch-gel electrophoresis, using the *tris*-borate-EDTA buffer, *p*H 8·4 (ref. 2), and phosphate buffer, *p*H 7·4 (ref. 3), starch-block electrophoresis with barbital buffer, *p*H 8·6 (ref. 4), hybridization both with abnormal haemoglobins and interspecific[5,6], and fingerprinting, according to Ingram as modified by Baglioni[7].

The propositus was a 5-year-old Negro child from West India. He was admitted early in 1964 to this hospital for a corticoid-resistant thrombocytopenic purpura. He was moderately anaemic, having 3,500,000 red blood cells/mm³, but there were no cellular abnormalities. Moreover, no abnormality was found in the blood of the mother. The father was not available for blood analysis.

a *b* *c* *d*

Fig. 3. Interspecific hybridization with canine haemoglobin. *a*, A + canine mixture; *b*, the same after hybridization; *c*, mixture between canine and (supposed) G after hybridization; *d*, same mixture without hybridization

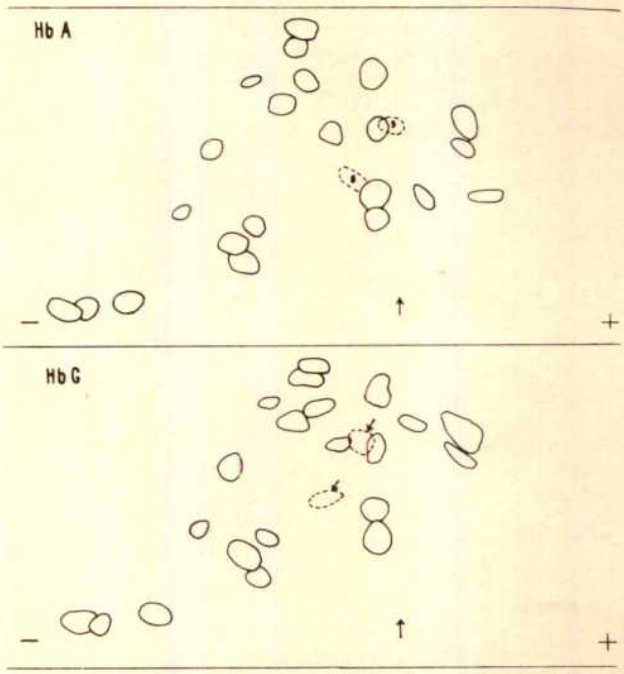

Fig. 4. Comparison of fingerprints of A and G haemoglobins. Peptides 3 and 9, which are displaced, were identified as methionine and histidine by specific stainings

We were able to observe by starch-gel electrophoresis two major components, one of them migrating more slowly than A, similar to haemoglobin G. Two minor components were also detected by *o*-dianisidine staining; one of them was A_2 while the other had a lower R_F. The result strongly suggested that the abnormality was located on the α-chain[8]. This was confirmed by hybridization experiments, and when haemoglobin G and haemoglobin S were dissociated together it was possible to obtain haemoglobin A and a slow abnormal hybrid.

$$\alpha_2^G\beta_2^A + \alpha_2^A\beta_2^S \quad \alpha_2^G\beta_2^A + \alpha_2^A\beta_2^S + \alpha_2^A\beta_2^A + \alpha_2^G\beta_2^S$$

Interspecific hybridization with canine haemoglobin have evidence for a fast hybrid $\alpha_2^{can}\beta_2^A$ with a mobility similar to that of the hybrid obtained with normal haemoglobin A. Conversely, the slow hybrid $\alpha_2^G\beta_2^{can}$ was slower than the hybrid of the normal haemoglobin, α_2^A.

Finally, fingerprinting showed displacement toward the cathode of two peptides, peptide 3 (α *T* IX) and peptide 9 (α *T* IX + free lysine or α *T* VIII). The latter peptide is similar to the former, but has only one supplementary

lysine 61 residue; tryptic digestion between the lysine and peptide α *T* IX was incomplete.

The α *T* IX peptide contains 29 residues (62–90). Only one haemoglobin G has so far been described (haemoglobin $G_{Philadelphia}$)[9] in which asparagine is replaced by lysine. But the pattern described is not similar to that which we found. The presence of one more lysine gives rise to three peptides instead of two, and the new peptides *G-3b*, *G-3b* ox., *G-9a*, show chromatographic as well as electrophoretic displacement.

In our patient, both peptides 3 and 9 were electrophoretically, but not chromatographically, displaced, and we only found two peptides. Our results are not compatible with the substitution of a neutrally charged amino-acid by one with a positive charge. Therefore, the most plausible mechanism would be the substitution of a negatively charged amino-acid by a neutral one; this substitution could well occur at the level of aspartic acid 64, 74 or 85.

IMMUNOLOGY

Failure of the Antibody Method to demonstrate a Circulating Hormonal Factor after Partial Hepatectomy

Although the extremely rapid regeneration of the liver that occurs after partial hepatectomy has been known for many years[1], the mechanism remains obscure. Many authors have suggested that the cell proliferation is due to a hormonal factor which appears in the blood following this procedure.

The evidence for this is based on the following claims: (*a*) Injections of serum taken from partially hepatectomized rats stimulate mitoses in a normal rat, or accelerate regeneration in another partially hepatectomized rat[2–5]. These claims have, however, been denied[6–8]. (*b*) Partial hepatectomy in one parabiont causes signs of regeneration in the partner[9,10]. Several groups have failed to confirm these findings[11–14]. (*c*) An autograft of liver with a satisfactory new blood supply will show growth stimulation if a partial hepatectomy is performed on the remaining original liver mass[15,16].

It is clear that, although the evidence is conflicting, the presence of a circulating hormonal growth-stimulating factor after partial hepatectomy cannot be excluded. It was considered possible that such a factor might be a protein or polypeptide, in which case it should be practicable to neutralize this by the action of a specific antibody.

Adult male Wistar rats were subjected to a 65 per cent partial hepatectomy by the standard method[17]. 24 h later, when mitotic activity in the liver is just beginning[18], blood was obtained from either the aorta or the portal vein; the latter source was used in view of the possibility that the hypothetical factor might be produced in the viscera drained by the portal vein. Rabbits were immunized with these sera mixed with Freund's adjuvant, according to the schedule of Peetoom[18]. 10 days after the final injection the rabbits were bled. The antisera were tested on an Ouchterlony plate against normal rat serum and post-hepatectomy serum, and were then absorbed with normal rat sera to remove non-specific antibodies.

In order to test the biological activity of these absorbed sera, rats and mice were partially hepatectomized between 2.0 and 4.0 p.m. Serum was injected into the peritoneal cavity at the finish of the operation, then at 10.0 a.m. and 4.0 p.m. the following day, and again at 10.0 a.m. on the second post-operative day. The last injection was accompanied by the subcutaneous injection of colchicine (100 μg for mice, 300 μg for rats). At 4.0 p.m. (that is, 48 h after the partial hepatectomy) the animals were killed, and the liver remnants, after weighing, were fixed in Bouin's fluid. The regeneration on a wet-weight basis and the mitosis count were estimated according to methods described earlier[20].

After several months' immunization, pooled antisera from three rabbits produced marked precipitation reactions with normal rat serum when tested on the agar plate. Normal serum and post-hepatectomy sera gave the same precipitin patterns with the antiserum. This does not, of course, exclude the presence of a specific factor in the post-hepatectomy serum, as an antigen–antibody complex may be soluble, or if insoluble, it may be present in amounts too small to form a visible precipitate.

Table 1. Effect of Antisera on the Regenerating Liver of Mice and Rats 48 h after Partial Hepatectomy

Experimental groups	No. of animals	Percentage of regeneration (wet weight) ± *S.E.*	Percentage of mitosis count ± *S.E.*
Mice			
Control (saline)	36	63·3 ± 3·8	3·06 ± 0·37
Normal human serum	36	73·1 ± 4·1	2·09 ± 0·44
Combined aortic (4) and portal (13) antiserum	17	74·6 ± 6·5 (0·20 > *P* > 0·10*)	2·01 ± 0·56 (0·20 > *P* > 0·10)*
Rats			
Controls (no injections (6) and normal serum (6))	12	63·6 ± 4·7	4·75 ± 0·55
Portal antiserum	10	60·8 ± 9·8	6·92 ± 1·05 (0·10 > *P* > 0·05)

* Compared with saline control.

The biological effects of the antisera are summarized in Table 1. The mice were injected with a total of 2·0 ml. of absorbed antiserum and the rats with 4·0 ml. of serum. It will be seen that no significant effect was produced. Regeneration on a wet-weight basis was slightly elevated in the mice and slightly depressed in the rats; neither change is statistically significant. The mice showed a fall in the percentage of parenchymal cells in mitosis; this also is not significant, and in any event injection of normal serum produced a similar value. In the rats there was actually a very slight rise in the mitosis rate.

Many workers have shown that antibodies can be produced to a wide variety of hormones. It is true that frequently the antigen used has been a relatively concentrated hormone; however, in some instances hormone-rich serum has been used as the antigen; for example, for the production of antigonadotrophin by the injection of crude pregnant mares' serum[21]. Hence the failure to demonstrate biologically active antibodies in the present experiments must be considered as strong, but not conclusive, evidence against a circulating protein or polypeptide factor stimulating liver regeneration. The existence of a non-protein hormone obviously remains open, and other possibilities are that partial hepatectomy causes a lowering of concentration of an inhibitor normally present in serum, or that hormonal factors in the circulation do not play a part in the mechanism of liver regeneration.

Complement Fixation and *p*H

IBE and Wardlaw have re-investigated the effect of *p*H on the activity of complement[1]. They confirmed previous reports[2] that the haemolytic activity of complement decreases with increasing *p*H and, in addition, presented evidence that complement fixation increases with increasing *p*H. They were able to increase the complement fixation titre of an antigen four-fold by raising the *p*H of the reaction mixture from 7·15 to 8·56. Stein and Van Ngu[3], however, showed that complement fixation titres can be increased by reducing the amount of complement used in the test. Thus, increased complement fixation sensitivity at relatively high *p*H may be due to loss of complement activity rather than to increased complement fixation. Experiments were devised to test this hypothesis.

Veronal buffer of *p*H 7·3 was prepared using the method of Kabat and Mayer[4]. Similar buffer was made to *p*H 8·3 by adding less hydrochloric acid. The conductivities of the two buffers differed by less than 2 per cent. Two chessboard (two-dimensional) complement fixation tests were performed with bovine serum albumin (BSA) and rabbit anti-BSA, one at *p*H 8·3 and one at *p*H 7·3. Both tests were performed with five 50 per cent units of complement. To supply this number of units in each test, more guinea-pig serum had to be used at *p*H 8·3 to compensate for the reduced activity of complement at the higher *p*H. Standard complement titrations were performed to determine the dilution of guinea-pig serum yielding five 50 per cent units of complement at each *p*H. Except for the differences in *p*H and absolute amount of guinea-pig serum used in each test, all other conditions were the same. Under these conditions the results of the two chessboard titrations were identical.

The next experiment was a direct test of the hypothesis that increased sensitivity of complement fixation tests at relatively high *p*H is due to reduction of complement activity. Four antibody titrations were performed with the optimal concentration of antigen found in the two-dimensional complement fixation tests. Parallel rather than serial dilutions were used and the extent of lysis in each reaction mixture was determined spectrophotometrically. Two of the antibody titrations were carried out at *p*H 7·3, one of them with five and the other with four 50 per cent units of complement. Similarly, two titrations were carried out at *p*H 8·3, one with five and the other with four 50 per cent units. The results in Table 1 show that the complement fixation antibody titres vary with the number of units of complement in the test. The apparent increase in complement fixation sensitivity at *p*H 8·3 was precisely duplicated at *p*H 7·3 by reducing the number of 50 per cent units of complement in the test from five to four. The choice of four 50 per cent units of complement was based on the observation that five 50 per cent units of complement at *p*H 7·3 are reduced to four at *p*H 8·3. Thus, the apparent increase in complement fixation sensitivity can be accounted for entirely by the reduced activity of complement at high *p*H. It must be concluded, therefore, that a change in *p*H in the range tested has no intrinsic effect on the efficiency of complement fixation. Sensitivity may be increased by alterations in procedure (for example, changes in *p*H or ionic strength), which inactivate complement, but the same result may be achieved under better control merely by using less complement.

Table 1

No.	Complement				Percentage of haemolysis			
					As 1/5,760–Ag 1/13,600		'1/5-control'	
	*p*H of complement fixation test	50 per cent complement units at *p*H 7·3	50 per cent complement units at *p*H 8·3	Guinea-pig serum dilution	Duplicates	Average	Duplicates	Average
1	7·3	5	4·0	1/109	56·6 49·1	52·8	56·6 56·6	56·6
2	8·3	5	4·0	1/109	39·0 35·6	37·3	33·8 26·9	30·3
3	7·3	4·0	—	1/137	31·6 33·8	32·7	25·4 25·4	25·4
4	8·3	—	5	1/86	52·5 45·0	48·7	55·0 55·0	55·0

No. of units of complement in each test is underlined.

A single lot of guinea-pig serum was used throughout. Complement titrations were performed in a reaction mixture of 7·5 ml. at *p*H 7·3 and at *p*H 8·3. The titres were 219 50 per cent complement units at *p*H 7·3 and 173 50 per cent complement units at *p*H 8·3, a ratio of 5·0 : 4·0.

Complement fixation tests shown in Table 1 were performed with 0·4 ml. BSA 1/13,600; 0·4 ml. anti-BSA 1/2,880, 1/5,760 or 1/11,520; and 0·5 ml. of the appropriate complement solution. The total volume of each reaction mixture, following the addition of 0·2 ml. optimally sensitized sheep erythrocytes, was 1·5 ml. (ref. 5). BSA 1/13,600 was the optimal antigen dilution found in the chessboard titrations which showed an antibody titre of 1/5,760. The reaction mixtures containing anti-BSA 1/2,880 showed no lysis, those containing anti-BSA 1/11,520 showed complete lysis, and those containing anti-BSA 1/5,760 are represented in Table 1. Anti-complementary control mixtures containing only antiserum or antigen, in the presence of three 50 per cent complement units, showed complete lysis. Stock BSA contained 2·5 mg protein/ml.

Each '1/5-control' contained 1/5 the amount of complement solution used in its corresponding test. These controls contained neither As nor Ag. '2/5 controls', containing 2/5 the amount of complement solution, were almost completely lysed. 3/5, 4/5, 5/5 controls were completely lysed.

New Methods of identifying Serum Siderophilin using Radioactive Iron

In earlier investigations of the immunoelectrophoretic identification of the iron-binding protein siderophilin or transferrin, pure preparations of the protein have been used[1–3]. The preparation of siderophilin is, however, difficult in spite of the fact that methods have been perfected to do this; for example, precipitation with rivanol[2,4]. Wuhrmann and Jasinski[8] were able to show siderophilin in paper electrophoresis by labelling it with radioactive iron. Paper electrophoresis, however, only allows the classification of siderophilin into a specific group of serum proteins, that is, the β-globulins.

In the present experiments, radioactive iron was used for detecting siderophilin in immunoelectropherograms of sera. The method made possible not only the classification of siderophilin into a specific group of proteins, but also the exact identification of the siderophilin arch.

Precipitating sera were obtained from rabbits weighing about 3,500 g, which were immunized with fresh rat and horse sera. Bentonite was used as adjuvant[5]. Adjuvant was mixed with an equal volume of serum. Three days after the last (fifteenth) injection, the serum levels of precipitins were checked in the immunized animals, which were then bled. The sera (with merthiolate added in the proportion 1 : 10,000) were stored at −20° C. Equine precipitating serum No. 512 (from the Pasteur Institute, Paris) was used in the study of human sera.

The isotope iron-55 (half-life 2·94 years) as the chloride in weak solution of hydrochloric acid (Radiochemical Centre, Amersham) was used. To 1 ml. of serum, 0·2 μc. of iron-55 was added, and the mixture was incubated in the refrigerator for 1 h.

The method of Scheidegger[6], as modified by Hirschfeld[7] using agar gel, was adopted. Mixtures of sera with iron-55 were separated electrophoretically for 2·5 h. The precipitating sera described above were used to precipitate proteins. The preparations were washed and dried and, after making autoradiograms, were stained with amide black.

Foton–Roentgen 'Super Films' were used for autoradiography. The preparations obtained by immunoelectrophoresis were covered by roentgen films of dimensions equal to those of the preparation and were exposed for 4 weeks.

After saturating the serum with radioactive iron, immunoelectrophoretic preparations and their autoradiograms were obtained and compared with each other. In the autoradiograms, iron-binding protein gives bright arches.

In Fig. 1, the immunoelectrophoretic pattern of normal human serum (*b*) and the autoradiogram of the same preparation (*a*) are illustrated. The autoradiogram contains a single bright arch, which is an exact reflexion of the arch of iron-binding protein precipitated in the immunoelectropherogram. The arch lies in the β_1-globulin region and is situated near the ditch containing the precipitating serum. Its localization in our experiments is analogous to

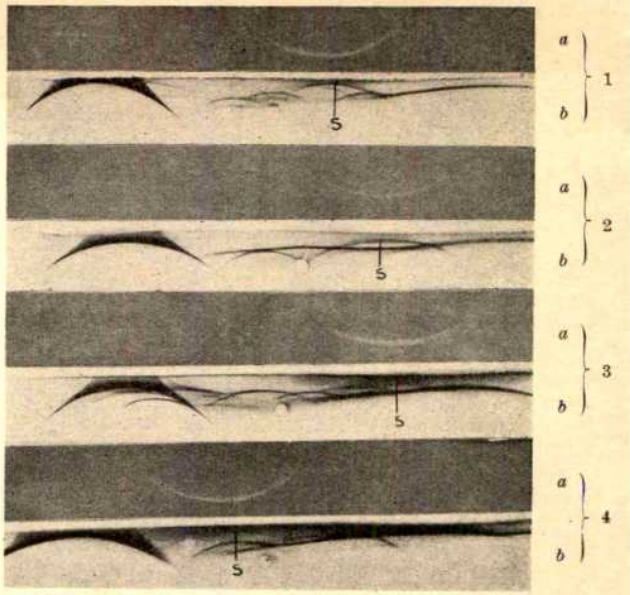

Fig. 1. *a*, Autoradiogram of siderophilin of human serum; *b*, immunoelectropherogram of normal human serum

Fig. 2. *a*, Autoradiogram of siderophilin of horse serum; *b*, immunoelectropherogram of normal horse serum

Fig. 3. *a*, Autoradiogram of siderophilin of rat serum; *b*, immunoelectropherogram of normal rat serum

Fig. 4. *a*, Autoradiogram of siderophilin of sheep serum; *b*, immunoelectropherogram of normal sheep serum

that obtained by Grabar and Burtin[1], Polonovski *et al.*[3], and Kistler *et al.*[2], who utilized pure preparations of siderophilin.

Siderophilin in the autoradiogram of horse serum is also situated in the β_1-globulin region (Fig. 2), and its arch is identical with the β_1-globulin arch in the immunoelectropherogram nearest the ditch containing the immune serum.

The siderophilin in rat serum shows different electrophoretic mobility, lying in the β_2-globulin region (Fig. 3). In the same way as in the preceding serum preparations, the arch of siderophilin of rat serum lies nearest the ditch containing precipitin.

Preliminary experiments showed that the electrophoretic mobility of sheep-serum siderophilin corresponds to that of the α_2-globulins (Fig. 4).

For technical reasons, the isotope iron-55 (half-life, 2·94 years), which has very weak radiant energy, was used in our experiments, which made necessary long exposure of the photographic films. The exposure time can be shortened to several days[8], using the isotope iron-59 (half-life, 47 days), which has much higher energy of β-radiation than iron-55.

PATHOLOGY

Evidence for the Cell-free Transmission of chemically induced Mammary Carcinoma in the Rat

THE possibility that chemically induced cancer might be the result of the activation of a latent virus has been considered in the past. Some evidence has been reported[1] which indicates transmission of chemically induced tumours by subcellular materials prepared from the latter. Data implicating a virus aetiology of this class of tumours have been inconclusive[2].

In the investigations described here, we have attempted to produce mammary carcinomata in the rat with cell-free preparations derived from the same type of tumour induced in the rat by administration of 7,12-dimethylbenzanthracene (DMBA), as originally described by Huggins *et al.* and by Geyer *et al.*[3].

Female rats of the random-bred Sprague–Dawley strain, approximately 50 days old and weighing 130–150 g, were given a single oral dose of 20 mg DMBA. About 65 per cent developed single or multiple mammary carcinomata within a 6-month period. These tumours were used in the experiments described here.

Tumour tissue preparations from one rat were never pooled with those derived from another rat; however, in some instances, multiple tumours from the same rat were combined. Aseptic procedures were followed at all times. The tumour tissue was rinsed once in Hanks's balanced salt solution, minced with scissors, and the mince was divided into two portions. One portion was ground in a mortar with 'Alundum' in 0·15 M potassium citrate solution containing 1 mg per cent hyaluronidase. This extract was freed from tissue debris and cells by three cycles of centrifugation at 1,900*g*, 2,400*g*, and 12,000*g*, for 20, 20, and 10 min each, respectively. The supernatant from the third cycle of centrifugation was centrifuged at 73,000*g* for 1 h. The resulting pellet was suspended in 0·05 M potassium citrate to give a concentration of 0·5–1·0 g equivalents of the original tumour tissue per ml.

The second portion of the same tumour mince was rinsed twice with Hanks's solution and gently agitated as a suspension in a 0·25 per cent solution of trypsin for 1 h at 37° C. The trypsinized cells were washed twice in Hanks's solution and suspended in complete medium to a concentration of 5–10 × 10^5 cells per ml., and grown on glass in Brockway Flint prescription bottles at 37° C for 2–4 weeks. (The complete medium consisted of 55 per cent minimum essential medium, 30 per cent beef amniotic fluid, 15 per cent calf serum (heated at 56° C for 30 min), 100 U. penicillin per ml. and 100 μg streptomycin per ml. The *p*H was adjusted with a 7·5 per cent sodium bicarbonate solution. All ingredients were obtained from Microbiological Associates, Inc., Bethesda, Maryland.) When the cell sheets from a number of bottles became confluent, the cells and medium were collected and pooled. This suspension was frozen and thawed three times. The suspension thus obtained was centrifuged in the same manner as the first portion of the mince. The final pellet was resuspended in a volume of 0·05 M potassium citrate equivalent to 1/10–1/20 of the original volume of the culture fluid.

Inocula prepared from each tumour by both processes were injected into new-born female Sprague–Dawley rats. Groups of 10–15 new-born rats were each injected with 0·1 ml. of the inocula subcutaneously, intraperitoneally, or, in a few instances, with 0·025 ml. intracerebrally. The injected animals were weaned when they were 3 weeks old and palpated for the presence of tumours at bi-weekly intervals. New-born rats of the same sex and strain, serving as controls, were injected either with similarly concentrated extracts of liver–spleen–lung tissue from tumour-bearing rats, of rat embryo cell cultures, 0·05 M potassium citrate or with 1–10 × 10^5 intact trypsinized cells from DMBA-induced tumours. None of the 800 rats given the foregoing control materials developed mammary carcinomata during 9 months of observation. On the other hand, when inocula derived from 54 DMBA-induced tumours were injected into a total of 1,180 new-born rats, fourteen mammary carcinomata (identified by histological examination) developed from thirteen of the DMBA tumours within 9 months. The results of these experiments, presented in Table 1, show that: (*a*) the incidence of tumour response of the injected animals was very low even in the positive groups; (*b*) the average latent period was about 6 months; (*c*) tumour production was equally successful with tissue culture preparations and tumour tissue extracts; (*d*) tumours also resulted from the injection of extracts that were filtered.

Table 1. PRODUCTION OF MAMMARY CARCINOMATA BY INJECTING NEW-BORN RATS WITH PREPARATIONS DERIVED FROM CHEMICALLY (DMBA) INDUCED MAMMARY CARCINOMATA OF THE RAT

DMBA-induced tumours: Source of inoculum	DMBA-induced tumours: Route of injection	Tumour response: Latent period (days)	Tumour response: Tumour*/total
Cell culture	intraperitoneal; subcutaneous†	100; 224	2/9
Cell culture	intraperitoneal; intracerebrally†	187	1/6
Cell culture	intraperitoneal; intracerebrally†	205	1/12

Tumour tissue‡	intraperitoneal	141	1/12
Tumour tissue	intraperitoneal; subcutaneous†	171	1/12
Tumour tissue	intraperitoneal	178	1/11
Tumour tissue	intraperitoneal	193	1/12
Tumour tissue	intraperitoneal	201	1/15
Tumour tissue	intraperitoneal	210	1/22

* Histologically, all tumours were papillary carcinomata or adenocarcinomata.

† Same animal injected by two routes.

‡ Filtered through 'Millipore *HA*' filter impermeable to bacteria (0·45μ).

The small number of tumours obtained in the experimental groups would seem to be significant, however, since none developed in control animals during the same period of time. Further investigations are being undertaken in an attempt to increase the tumour incidence.

Deoxyribonucleic Acid Synthesis of Hydatidiform Moles in Organ Culture: an Autoradiographic Investigation

MIDGLEY *et al.*[1], using tritiated thymidine, have demonstrated that placental syncytiotrophoblast in the monkey originates from cytotrophoblast. Electron microscopic and immunochemical investigations of benign and malignant trophoblast have supported this concept and have also shown that the differentiated syncytiotrophoblast produces chorionic gonadotrophin[2–4].

A hydatidiform mole is a chorionic growth which morphologically and clinically represents an immature and pathologic trophoblast[5,6]. In the investigation reported here, an attempt was made to label selectively and to follow the maturation pattern seen in trophoblast

from vesicles of hydatidiform moles incubated in organ culture. Tritiated thymidine was chosen as the label, as it is incorporated into newly synthesized DNA in the normal cytotrophoblast[1].

Twenty vesicles of two hydatidiform moles were obtained in the delivery room from women with histories of 13 and 15 weeks of molar pregnancy, respectively. The vesicles were incubated in tissue culture medium 199 with 1 μc. ^{3}H-thymidine per ml. of culture.

Vesicles were recovered from the culture at intervals of 3, 6, 12 and 24 h, fixed in Bouin solution, embedded in paraffin, sectioned at 6μ and coated with Kodak '*NTB* 3' emulsion. After sufficient exposure at 4° C in plastic boxes, the slides were developed and stained with haematoxylin and eosin.

Irregular distribution of silver grain deposits was observed in the cytotrophoblast of vesicles lined by two rows of trophoblast cells, but no label was present in syncytiotrophoblast nuclei. Areas with hyperplasia or anaplasia of the trophoblast showed irregular labelling of cytotrophoblast nuclei in different areas, but there was no evidence of labelling in the syncytiotrophoblast. Labelling of the trophoblast greatly increased in those vesicles that had been left for 24 h in organ culture. A large number of Hofbauer cells and other stromal cells were also labelled by radioactive thymidine (Fig. 1).

When the percentage distribution and variance of the marked nuclei were plotted against the incubation time of the vesicles, an increased proportion of the labelling was found. The same proportion of label was also observed in thin areas of trophoblast as in areas of hyperplasia (Table 1).

These findings suggest that the cytotrophoblast of hydatidiform moles, although it exists in an irregular form, contributes to the formation of syncytiotrophoblast, and that inactive-looking portions of trophoblast seem to be potential areas for developing hyperplasia, as they incorporate thymidine in the same proportion as does hyperplastic trophoblast. Although it might be expected to be active, the latter does not show any greater proportion of any label than do thin areas of trophoblast. It is possible that this finding indicates an alternating capacity for cellular reproduction in these tissues. The presence of labelled nuclei of stromal cells indicates an active incorporation of thymidine; the proportion found was not expected, as mitoses are infrequent in these cells.

Table 1. Percentage of Localization of Tritiated Thymidine in Nuclei of Hydatidiform Moles

Nucleic Acids of Malignant and Benign Splenic Hyperplasias in Mice

Cerecedo *et al.*[1–3] and Hilf *et al.*[4], studying the effect of sarcoma 180, melanoma *S*91 and stressing agents on the nucleic acid content of different organs of the mouse, found that the RNA/DNA ratio usually dropped with the growth of the tumours.

In transplanted murine leukaemias the RNA and RNA : DNA ratios were increased in the spleen[5]. Moreover, when the nucleic acids of splenic cells of spontaneous and transplanted leukaemias were investigated, only the RNA was found to be increased in the former, while both DNA and RNA as well as the nitrogen content were augmented in the latter[6]. In induced leukaemias, Rich *et al.*[7] observed that splenic RNA was higher than in the controls.

The work reported in this communication was devised to investigate whether there is any significant quantitative difference in the nucleic acid content of malignant hyperplasias as compared with benign processes, and if so, how do these changes develop with time.

Groups of 5–10 male *BALB* mice about 3 months old were intraperitoneally injected with a cellular homogenate of either a leukaemia (*L*423) or a lymphosarcoma (*L*370). Animals were killed at 2 h, 1, 3, 5, 7 and 10 days after the injection.

Splenic nucleic acids were extracted according to the technique developed by Schneider[8]; RNA was determined by the orcinol reaction as modified by Ceriotti[9] and DNA by a colorimetric method based on the diphenylamine reaction described by Dische[10]. Each determination was repeated three times and compared with the corresponding standard solution; the results are expressed in mg per mg wet tissue. Three groups of controls were used: (1) spleens of normal mice injected intraperitoneally with normal *BALB* splenic cells; (2) spleens of mice injected intraperitoneally with 0·2 ml. of Freund's adjuvant; in this case specimens were obtained over a period of 90 days; (3) spleens of

mice injected subcutaneously with 0·2 ml. of a 1 per cent phenylhydrazine hydrochloride (PH). When the determination of nucleic acids in the spleens of those animals transplanted with *L*423 and *L*370 had been carried out and related to the evolution of the process, it was observed that while RNA disclosed a gradual increase, significant only in the case of *L*423, DNA had a tendency to decrease although the drop was not significant. These modifications in the nucleic acids were more clearly demonstrated by the RNA : DNA ratio, which rose with time in *L*423 (F, 21·3; $P < 0.01$) and *L*370 (F, 9·73; $P < 0.05$) (Fig. 1).

When the same determinations were carried out in those animals injected with normal splenic cells, no changes in the nucleic acids were detectable ($P > 0.4$; > 0.3).

When PH was administered, although DNA and RNA both showed a non-significant transitory increase, the RNA : DNA ratio disclosed a progressive and significant fall (F, 12·8; $P < 0.05$) (Fig. 1).

When Freund's adjuvant was injected, although the splenic RNA showed a slight tendency to increase while the DNA tended to decrease, neither of them varied significantly. However, the RNA : DNA ratio showed a transitory and significant increase in the first 10 days (F, 10·4; $P < 0.05$) (Fig. 1), after which it levelled off again. In Fig. 2 the various RNA : DNA ratios are plotted against the log spleen weight, and since the slopes of both benign hyperplasias are similar their values have been pooled. The remaining slopes are significantly different (F, 5·67; $P < 0.01$). When the values of RNA : DNA ratios are adjusted to a mean log spleen weight common to all groups, their difference is highly significant (F, 7·8 ; $P < 0.01$). This means that for the same log spleen weight the RNA : DNA ratio is greater in the two malignant groups.

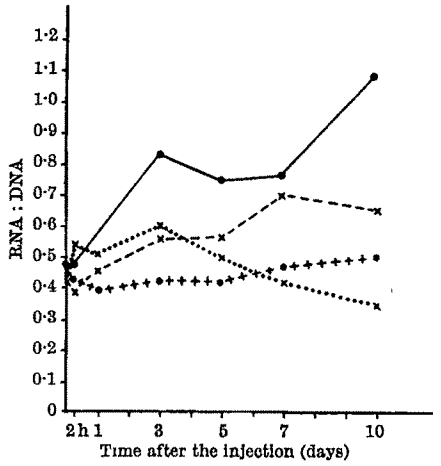

Fig. 1. RNA : DNA ratios in benign and malignant hyperplasias plotted against time Fitting the curves by lineal regressions the significance of the slopes are: Lymphosarcoma (*L*370), F, 9·73, $P < 0.05$ (●——●); leukaemia (*L*423). F, 21 3, $P < 0.01$ (× — ×); Freund's adjuvant (FA), F, 10·4, $P < 0.05$ (● + + + + ●); phenylhydrazine hydrochloride (PH), F, 12·8, $P < 0.05$ (× ···· ×). Note that phenylhydrazine hydrochloride has, in part, a negative slope

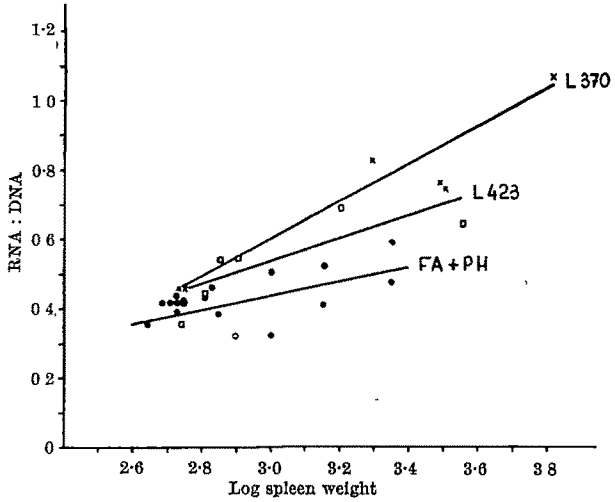

Fig. 2. RNA : DNA ratios in benign and malignant hyperplasias plotted against log spleen weight. These curves proved linear and their slopes are significantly different (F, 5·67, $P < 0.01$). The values of Freund's adjuvant and phenylhydrazine hydrochloride have been pooled because their slopes are not significantly different

It is possible to assume, according to these experiments, that the increases observed in animals injected with *L*423 and *L*370 are related to the malignant nature of the processes and not only due to splenic hyperplasia or rapid growth, as postulated by Peterman[6]. In fact, mice treated with PH showed an increase in spleen weight comparable with or even greater than that seen in the malignant groups. It is also of interest to note that with *L*423 splenic RNA showed a gradual and progressive increase; however, Peterman[5], working with a transplantable leukaemia, reported that RNA, although increased, did not change with the evolution of the disease. In conclusion, the malignant processes studied in these experiments show a definite modification in the RNA : DNA ratios which seems to be characteristic of malignancy since no similar degree of alteration was observed in the benign hyperplasias when related either to spleen weight or time of evolution.

BIOLOGY

Normal Distribution of Cell Generation Rates

The distributions of generation time are markedly skewed, but the reciprocal of the generation time, termed 'generation rate', was reported to have a normal distribution for a bacterium, yeast, a strain of human tissue culture, and the protozoan *Tetrahymena geleii*; these results provided evidence for the generalized nature of this distribution in widely different kinds of cells in balanced growth[1]. Although other measurements had not always given a normal distribution of generation rates, this was to be expected since the sources of experimental bias were not then completely understood. There are several kinds of bias that must be avoided[2]. Furthermore, some experiments in the literature have given no clear test of the nature of the distribution, since data are insufficient, with rather fewer than 100 cell divisions measured. Nevertheless, it has been asserted that the skewed character of the generation-time distribution has decreased as experimental techniques have advanced[3], and this would require that the generation rates depart from a normal distribution. This communication presents further evidence for the validity of the normal distribution for generation rates.

In an extensive study of the individual generation times of another protozoan, *Euglena gracilis*, grown either in a salt medium (790 cells) or in a complex organic medium (548 cells), Cook and Cook observed skewed distributions of generation time[4]. Their data (kindly sent to me) provide excellent evidence for normal distributions of generation rate for *Euglena* in each of these media, and are replotted in Fig. 1. It may be seen from this that there is no significant departure from the normal distribution for generation rates as small as three standard deviations below the mean (in each case the lower three points are the sums of one, two, and two observations respectively) and for generation rates as large as two standard deviations above the mean. The remarkable agreement at rapid rates was unexpected, since it seemed obvious that some maximum rate must exist for cell reproduction. Clearly, these data strongly support the normal distribution of generation rates, modified only at large generation rates by the requirement of a minimal time for the completion of the cycle of cell division.

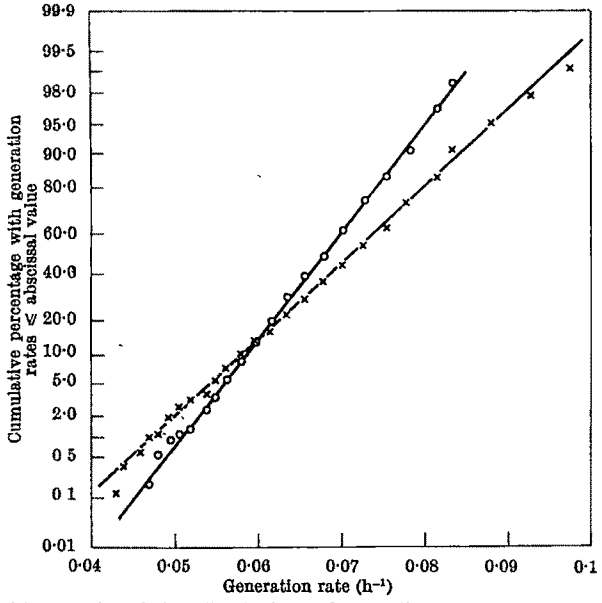

Fig. 1. Cumulative distributions of generation rates for *Euglena gracilis*. The data of Cook and Cook[4] are plotted as cumulative distributions of generation rates on arithmetic probability coordinates. ×, Cells growing in a salt medium; ○, cells growing in a complex organic medium

It should be pointed out, however, that the cell interdivision times are not independent from one generation to the next: the data for *Escherichia coli*[1] fail to show the required increase in standard deviation of the sums of the times of successive divisions[5]. A more complete analysis is in progress.

Finally, the results of Cook and Cook partially modify an earlier suggestion of mine that the control of cell division might tend to fall into either of two classes under conditions of balanced growth[2]. The average values of the coefficient of variation of generation rate ($C.V.$) that had been observed for the two classes (along with their standard errors) were 9·4 (±0·2) per cent and 18·8 (±0·6) per cent. For *Euglena* grown in organic medium the value of $C.V.$ is 10·6 (±0·3) per cent, which tends to fall into the first group above. However, the value with the salt medium is 16·0 (±0·4) per cent, which does not fall into either group. Thus, it is apparent that the variability in cell division can be modified by environmental conditions, even for cultures in balanced growth.

These results can readily be understood if the generation time depends on several or many reactions, any one of which might be transiently rate-limiting for cell replication. For cells growing in a complex organic medium the number of different kinds of reactions that the cell must carry out will be reduced by the exogenous supply of compounds that would otherwise necessarily be synthesized. Here, the ready availability of these compounds would reduce the time necessary for cellular replication, eliminating the contribution of these reactions to the over-all generation time and thereby decreasing the value for $C.V.$

The clustering of values of $C.V.$ which remains when cells are allowed to grow at nearly maximum rates suggests, further, that the residual variability in generation rates might arise essentially from the variability remaining in a single process; for example, the time needed to replicate DNA. The mechanism by which some cells achieve tight control of cell division (that is, $C.V. \approx 9{\cdot}5$ per cent) while others have their cell division only poorly controlled ($C.V. \approx 19$ per cent) is not known. However, further evidence that there are two discrete states of the control of cell division has been obtained for the yeast *Saccharomyces cerevisiae:* either of two values of $C.V.$ is obtained over a temperature range[6].

Prolactin and Serum Osmolality of Hypophysectomized Killifish, *Fundulus heteroclitus*, in Fresh-water

The presence of the pituitary[1], or, more specifically, the presence of the erythrosinophilic cells of the proadenohypophysis[2], is necessary for fresh-water survival in the euryhaline cyprinodont, *Fundulus heteroclitus*. Failure, with symptoms of asthenia, is correlated with a fall in serum chloride. Hypophysectomized *F. heteroclitus* can be maintained in fresh-water by intraperitoneal injections of *Fundulus* pituitary brei. Crude pituitary preparations from other species may be partially effective (perch, rat). Replacement therapy with synthetic or partially purified hormones led to the discovery that mammalian adenohypophyseal preparations with prolactin activity can prevent failure[3,4]. Purified ovine prolactin was highly effective, and significant prolongation or maintenance of survival was observed with bovine prolactin and with primate growth hormone preparations containing prolactin activity. Ovine prolactin also prolongs fresh-water survival in hypophysectomized *Poecilia latipinna*[5], *Xiphophorus maculatus*[6], and *Tilapia mossambica*[7].

Preliminary data, reported in this communication, demonstrate that injections of ovine prolactin, at a suitable dose, enable hypophysectomized *F. heteroclitus* to maintain normal serum osmolality. Serum was taken from selected groups of fish the failure or survival of which in fresh-water has been the subject of a separate communication[4]. Osmolality was estimated on 6–15 μl. samples, from individual fish, by comparison with standard sodium chloride solutions, using a 'Mechrolab' vapour pressure osmometer equipped with Hamilton microsyringes. The results are expressed in terms of equivalent osmolality (Table 1).

Normal values for serum osmolality of hypophysectomized *F. heteroclitus*, maintained in salt-water, averaged 0·372. This is in the expected range for intact fish under similar conditions. Effective treatment with ovine prolactin (105 mU./g, alternate days) resulted in essentially similar values for the serum of hypophysectomized fish maintained for 28 days in fresh-water. In contrast, low levels were observed in the serum of fish taken at the onset of asthenia (tilting) in fresh water. This datum was

obtained from fish that had received ineffective replacement therapy: four fish had been treated with bovine growth hormone and had failed in 6–10 days; five fish treated with arginine vasotocin (0·0225 mU./g daily) had failed even more rapidly. Monkey growth hormone, containing prolactin activity equivalent to 40 mU./g on alternate days, prolonged survival but failure ensued in 18–22 days. Ovine prolactin administered at a high dose (350 mU./g, alternate days) was less successful than the lower dose reported here: one fish that failed after 17 days had a serum osmolality of 0·252; another that was still alive after 22 days in fresh-water had a serum osmolality of 0·289. This may be near the lower limit for survival, since one fish receiving arginine vasotocin failed with a serum osmolality of 0·265, the highest recorded at onset of asthenia.

These results may be compared with Burden's[1] data for serum chloride: hypophysectomized *F. heteroclitus* in salt-water averaged 152 mM Cl/l., hypophysectomized *F. heteroclitus* at onset of asthenia in fresh-water averaged 66 mM Cl/l. It is possible that Burden's fish were taken in a more advanced state of failure, as the serum chloride was 43 per cent of normal, whereas, in our experiments, the serum osmolality was 63 per cent of normal. Further clarification would require the simultaneous determination of all major solutes contributing to serum osmolality.

The failure of teleostean neurohypophyseal peptides to prolong fresh-water survival in hypophysectomized *F. heteroclitus*, documented in the article already cited[4], is associated with a concomitant inability to maintain serum osmolality, reported in the present investigation. In contrast, ovine prolactin, which was highly effective, contained little or no activity that would indicate the presence of contaminating traces of neurohypophyseal hormones.

The mode of action of prolactin requires further investigation. Restoration of impaired function of the mucus-secreting cells may be suspected. Removal of the mucous coating of the skin severely disturbs salt- and/or fresh-water tolerance in various teleostean species[6]. Burden reported atrophic changes in the mucous cells of the gills in hypophysectomized *F. heteroclitus*. On the other hand, prolactin stimulates the secretion of 'discus milk' in *Symphysodon discus*[9], and a single injection causes a transitory increase in the abundance of mucous cells in the skin of *S. aequifasciata axelrodi*[10]. Another possible contributory action has been reported: prolactin increases urine flow and decreases urinary sodium concentration in hypophysectomized *Fundulus kansae*, maintained in hard tap water[11]. The impaired kidney function of hypophysectomized fish is, in this respect, restored to normal. Furthermore, in agreement with our findings on *F. heteroclitus*, prolactin enables *Poecilia latipinna* to maintain serum sodium at near normal levels, 24 h after hypophysectomy in fresh-water[12]. Osmoregulatory processes are more primitive in myxinoids, and the failure of prolactin to increase the diminished serum sodium and potassium of intact hagfishes adapted to 60 per cent salt-water[13] may have no bearing on teleostean problems.

This investigation was supported by grants from the U.S. National Science Foundation (*GB*–0132, *G*–17660 and *AM*–01940) and by a general research support grant from the National Institutes of Health, U.S. Public Health Service.

Uncertainty of Leadership-rank in Fallow Deer

SOCIAL animals may have group 'leaders' which respond to external stimuli more rapidly than do other individuals, and thereby influence the behaviour of the whole group. Allee *et al.*[1] described leaders in a flock of pekin ducks, but noted only the frequency with which specific individuals led the rest of the group. Apparently no one has investigated ordering among the 'followers', so that it is not known whether the rest of a group tends to follow the leader in a definable sequence.

As part of a behavioural study[2] of the fallow deer (*Dama dama*), six pregnant does were penned and marked for individual identification at the Duke University Field Station for Animal Behavior Studies. When frightened, as by approaching persons, the does ran from one part of the enclosure to another along a length of fence. The sequence of individuals became stable shortly after their start and was noted at the midpoint of their travel by one of us (B. K. G.) on 101 occasions. Does were thus scored as rank one (first in line) to rank six on each occasion.

If each rank assignment is an x and there are n assignments the mean rank $(\bar{x})$ of each individual is:

$$\bar{x} = \frac{\sum_{n=1}^{101} x}{n} \qquad (1)$$

The uncertainty in rank of each individual (U_x) is computed from Shannon's[3] information equation in which the probability (p_i) of occurrence of rank i is estimated by the ratio of x's in i to the total number of x's (n), and the solution is in bits of uncertainty:

$$U_x = \sum_{i=1}^{6} p_i \, (-\log_2 p_i) \qquad (2)$$

Fig. 1 shows that stability in rank is very highly correlated with mean rank. Under the conditions of the experiment one can refer to a single group leader. However, other does do not merely comprise a group of followers; they tend to follow the leader in a linear sequence which becomes more variable as leadership-rank decreases. We cannot say from the present observations whether leadership-rank is related to dominance-rank in these individuals. Nor can we say whether the positive correlation of leadership-rank and rank-certainty is maintained in differently sized groups.

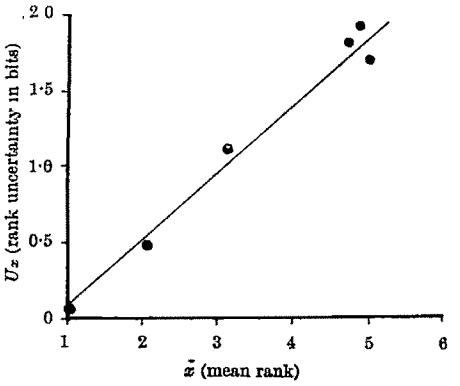

Fig. 1. The linear correlation between decreasing leadership rank ($\bar{x}$) and increasing uncertainty of rank (U_x). Each of the six points represents a particular doe of the herd. The line is fitted by eye

It is possible that differences in responsiveness—dependent primarily on individual physiological factors (for example, sensory capacities and response latencies) and psychological factors (for example, nervousness)—produce the observed sequences. Alternatively, the data may illustrate a parameter of social organization heretofore not predicted by behavioural theory.

We thank Drs. Klopfer and R. MacArthur for their assistance. The study received support from National Institutes of Health grant *M*–4453, and was completed during tenure of National Institutes of Mental Health predoctoral and postdoctoral fellowships to J. P. H.

Metabolism of *Spirogyra* during the Conjugation Process

Metabolic changes corresponding with morphological change during the conjugation process of *Spirogyra* sp. were investigated.

The activity of endogenous respiration in intact cells was found to change during this process as seen in Fig. 1. The activities of NADH oxidase, NADH- and succinate-cytochrome *c* reductases, and cytochrome *c* oxidase were found to vary during the conjugation process in parallel

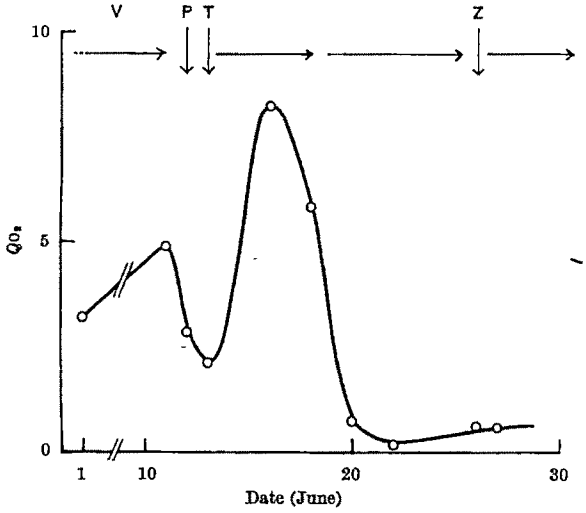

Fig. 1. Activity of endogenous respiration of *Spirogyra* sp. at different stages of the conjugation process. Conditions: intact cells, 200 mg wet weight; phosphate buffer, 0·02 M, *p*H 7·2; total volume, 2·0 ml; at 30° C

Table 1. Amounts of RNA and DNA in *Spirogyra* at Different Stages of Conjugation Process

Cells	Modified Ogur–Rosen method (refs. 1, 2)					Schmidt–Thanhauser method (ref. 3)				
	μg/mg dry wt.		μμg/cell		RNA/	μg/mg dry wt.		μμg/cell		RNA/
	RNA	DNA	RNA	DNA	DNA	RNA	DNA	RNA	DNA	DNA

with the change of respiratory activity. The amounts of oxygen evolved, the oxidative activity of reduced indigo carmine, and the activities of oxidation and reduction of cytochrome *c* in light, declined at the late conjugation stage both in intact and cell-free states.

The content of nucleic acids was also found to vary during the process (Table 1). The amount of DNA per mg dry weight of cells was increased by about 20 per cent in conjugation-tube formed cells (*T*-cells) and by about 200 per cent in zygote (*Z*-cells) compared with that of vegetative cells (*V*-cells), but there was not such a percentage increase of RNA. Calculation of the DNA content per cell showed that this was increased about 1·7-fold in *T*-cells and 3·4-fold in *Z*-cells compared with *V*-cells, while RNA was increased in *T*-cells and in *Z*-cells by about 1·4-fold and 2·7-fold, respectively. From these results one can see that the DNA and RNA per cell of zygote is approximately twice that of a *T*-cell. As shown in Table 1, the ratio of RNA to DNA in *T*-cells was the same as in *Z*-cells and less than in *V*-cells.

When the cells were growing and dividing normally, most of the cells observed by day were short in length (172–174μ) and elongated cells (342–344μ) were rarely observed. The width of both cells was about 115μ. The former were designated as 'short' cells and the latter as 'long' cells. It is of interest that *T*-cells were originated only from 'short' cells and not from 'long' cells, and DNA content of each 'long' cell was equivalent to that of a *T*-cell and about twice that of a 'short' cell. DNA in *T*-cells, half of which might be synthesized at the earlier conjugation stage, seems to be closely connected with conjugation-tube formation, because *T*-cells are formed without cell division and differ in length from 'long' cells.

Estimation of basic proteins in the larger particulate fractions (nuclear and chloroplast) showed a gradual increase during the conjugation process. From this fact, it may be assumed that the decline of enzyme activities, at the later stages of this process, is due to the action of some basic proteins depressing the formation of messenger-like RNA and of enzymes. Investigations on the properties of the basic proteins are in progress, and the details of this study will be published elsewhere.

We thank Prof. S. Usami for his advice during this investigation.

Variable Photosynthetic Responses of *Pinus resinosa* Seedlings to Herbicides

Herbicides have shown variable toxicity to young gymnosperms; the susceptibility of these plants greatly varies according to the chemicals and dosage used, the species, and the age of the plants[1–4]. Among the more obvious deleterious responses of young *Pinus* plants to certain herbicides are twisting and curling of cotyledons, distortion of old needles, chlorosis, and subsequent plant mortality. The incorporation of herbicides by the soil usually causes greater injury to plants than does the application of them to the soil surface[3,4]. Comparisons

of cross-sections of needles from young control *Pinus resinosa* and herbicide-treated plants showed marked effects on needle anatomy as a result of treatment[5]. Needles from control plants were approximately semicircular in outline. Their mesophyll cells were closely packed and infolded, and they contained large chloroplasts. In contrast, needles of plants treated with atrazine, simazine or prometryne were distorted and chlorotic. Their mesophyll cells were often rounded and the infolding characteristic of normal mesophyll tissue no longer occurred. Frequently the mesophyll cells became vacuolated or nearly empty and sometimes large gaps were present among them[5]. These experiments have now been extended in order to evaluate the effects of five structurally different herbicides on photosynthesis of 3–0 *Pinus resinosa* Ait. seedlings.

Experiments were performed in north-central Wisconsin, beginning in early June 1964, and continuing for up to 60 days. The length of time that a particular herbicide was tested depended on the plant response. If photosynthesis reached a negligible value after treatment measurements were then discontinued.

Herbicides tested included DCPA, EPTC, atrazine, 2,4-D, and monuron. Test plants, 15–20 cm in height, were grown out of doors in plastic pots containing sandy loam soil. Each treatment consisted of five replicates (plants) and five non-treated seedlings were used as controls. Each herbicide was applied at 20 lb./acre of active ingredient suspended in 50 ml. of water. This was carefully mixed into the soil of the potted seedlings. Plants were watered regularly. After treatment, each test plant was brought into the laboratory, at approximately weekly intervals, in order to measure the photosynthesis of the entire shoot; the seedling was then returned out of doors. Apparent photosynthesis was measured, for 10 min in a closed system, as the uptake of carbon dioxide, and for this purpose a Beckman 15*A* infra-red gas analyser was used. The seedling shoot was enclosed in a sealed metal photosynthesis chamber which had a glass window at the top. Light was provided by a single high-intensity lamp, and was 10,000 ft.-candles at the top of the chamber and 6,000 ft.-candles at the bottom. Temperature in the shoot chamber was maintained at 29°–30° C by using two layers of water filters.

The various herbicides showed marked differences in their effects on photosynthesis. In control plants the rate of photosynthesis increased gradually with each weekly measurement and by 5 weeks the uptake of carbon dioxide had increased by about half. This was apparently caused mainly by increased leaf area following bud opening and expansion of the new shoots. It is probable that the increase also reflected the increasing efficiency of chlorophyll and the improved conditions for photosynthesis—especially the increasing temperatures and the somewhat higher light intensities out of doors. Plants treated with DCPA showed very similar responses to control plants, and no significant differences were found between the two groups. Plants treated with DCPA showed a healthy green colour throughout the experiment.

In contrast to the treatment with DCPA, EPTC, atrazine, 2,4-D and monuron depressed photosynthesis to varying degrees. The photosynthetic rates of plants treated with EPTC increased very slightly for at least 2 weeks after the herbicide had been applied. However, as from the third week the photosynthesis decreased gradually until at 45 days the rate was only about a third of that shown by the control plants. The appearance of EPTC-treated plants was markedly different from that of plants treated with other herbicides. Thirty days after treatment with EPTC the new foliage showed slight chlorosis, while the old needles retained a healthy green colour. At 40 days, necrosis of new needles was observed—this being characterized by a bright, reddish-brown colour. Unlike the effects produced by treatment with other herbicides, this response progressed downward in the plant. Uptake of carbon dioxide was still detectable 57 days after treatment, by which time almost all the needles had turned brown and wilted.

Atrazine rapidly depressed photosynthesis, and no uptake of carbon dioxide was detectable after 4 weeks. Colour changes were already discernible 3 weeks after treatment and the 2-year-old needles appeared flaccid and yellow-green. At 4 weeks all needles were flaccid and yellow, and mortality soon occurred rapidly. Two of the plants were dead within 4 weeks and all five were dead within 5 weeks.

2,4-D also rapidly depressed photosynthesis, and the pattern of decline in photosynthesis was similar to that following treatment with atrazine. However, the colour changes were different, and plants treated with 2,4-D showed a whitish, bleached appearance in contrast to the yellow-green colour of those treated with atrazine. Photosynthesis was negligible 5 weeks after 2,4-D treatment. Some chlorophyll degradation was evident 2–3 weeks after treatment. At 4 weeks colour changes were conspicuous in the new needles and some abscission of leaves had occurred by that time. Leaf abscission did not ensue from treatment with any of the other herbicides.

Of all the herbicides tested, monuron depressed photosynthesis most rapidly. However, visible symptoms of damage to leaves following treatment with monuron were practically unnoticeable. Absorption of carbon dioxide could not be detected 11 days after treatment. At that time no change in leaf colour or condition was apparent. The needles were green even after 30 days, but after 40 days they were a weak green colour similar to those of the atrazine-treated plants.

These experiments once again emphasize the extreme variability of physiological responses of plants to different herbicides. Furthermore, they emphasize that the mechanism inhibiting photosynthesis varies from herbicide to herbicide, and that the depression of photosynthesis occurs with or without breakdown of chlorophyll.

Role of the Leaf in Flowering of Late Pea Varieties

Late (*Sn Sn*) pea varieties respond to long days and vernalization by flowering at a lower node[1]. Paton[2] suggested that the product of leaf area and photoperiod governs the first node at which flowering occurs. If this is so, defoliation treatments should have an effect on the node of first flower (*F*). I have conducted several experiments to test this hypothesis. In general, the only conclusion to be drawn from the results (those for a typical experiment are shown in Table 1) is that leaves apparently have little effect on flowering.

Recently, Cathey and Borthwick[3] have shown that the ratio of red to far-red light reaching the cells may be the controlling factor in flowering, by governing the concentration of physiologically active phytochrome. This ratio would not be affected by defoliation treatments and it thus appears likely that *F* is a function of photoperiod only, not of leaf area as well, provided that a minimum area is present for photoreception. The stipules of the pea plant, which were left intact during the present experiments, may well be adequate for this purpose since they contribute up to half the photosynthetic area.

Table 1. Effect of Defoliation at Nodes indicated (Cotyledonary Node taken as 0) on Node of First Flower (*F*) and Total Shoot Height of the Late Pea Variety, Greenfeast*

Nodes defoliated		*F* (node No.)	Height (cm)
None—control		16·27	31·0
3,4	*E*	16·15	27·8
3,4	*L*	15·76	26·4†
3,4,5,6	*E*	15·60†	25 0‡
3,4,5,6	*L*	15·60†	22·8‡
3,4,5,6,7,8	*E*	15·97	23·0‡
3,4,5,6,7,8	*L*	16·02	22 2‡
3,4,5,6,7,8,9,10	*E*	16·12	23 2‡
3,4,5,6,7,8,9,10	*L*	16·03	21·0‡

* Plants grown in 16 h photoperiod. *E* and *L* denote whether leaves were removed when just unfolding (*E*) or when expanded (*L*). Nodes 1 and 2 bear only scale leaves.
† Significantly different from control at 5 per cent level.
‡ Significantly different from control at 1 per cent level.

Table 2. Effect of Cotyledon Excision at Different Times after Germination (Day 0) on Node of First Flower (*F*) and Total Shoot Height of the Late Pea Variety, Greenfeast

Plants grown under natural long days (about 14 h) Age when cotyledons excised (days)	*F* (node No.)	Height (cm)
4	17·13 ± 0·20	26·38 ± 2·81
6	18·16 ± 0·19	33·32 ± 1·88
8	18 63 ± 0·21	49·54 ± 1·87
10	18·96 ± 0·20	52·00 ± 1·18
12	19 28 ± 0·26	51·68 ± 1·41
Control, cotyledons intact	19·71 ± 0·26	53·67 ± 1·12

Observed correlations between (leaf area × photoperiod) and *F* in intact plants may be due to vegetative growth processes and flowering being similarly affected by environment.

Severe defoliation treatments reduce vegetative growth. Similar results may be obtained by removing cotyledons during the early stages of growth. However, unlike the removal of foliage leaves, removal of cotyledons has a marked effect on flowering, reducing *F* (Table 2 and ref. 4). Comparison of Tables 1 and 2 suggests two points. First, that the observed differences in *F* cannot be explained by alterations in the rate of node formation, since vegetative growth is affected similarly, but flowering differently, by leaf and cotyledon removal. Secondly, that foliage leaves and cotyledons have distinct roles in the flowering process. Cotyledons, as first proposed by Barber and Paton[5], contain a flower inhibitor. This is quantitatively transported to the apex during the first 2 weeks of growth, as shown in Table 2. Foliage leaves are obviously involved in the photoperiodic response, but in a qualitative rather than a quantitative fashion, possibly by supplying both phytochrome and a substrate for its action[6]. The relationship between the effects of foliage leaves and cotyledons is not yet clear.

These experiments were carried out while I was in receipt of the Imperial Chemical Industries of Australia and New Zealand research fellowship of the University of Tasmania.

Chlorophyll Content of *Deschampsia flexuosa* Seedlings grown on a Calcareous and a Non-calcareous Soil

It is well known that many plants characteristic of acid soils become chlorotic when grown on calcareous soils. This phenomenon is usually referred to as lime-induced chlorosis and has been associated with impeded iron metabolism of the plants grown on calcareous soils. This communication describes an unusual alteration in the ratio of chlorophyll *a* to chlorophyll *b* in plants showing chlorosis. Seedlings of *Deschampsia flexuosa* were grown on a mor soil collected from the surface, 5 cm beneath a *Deschampsia flexuosa* litter layer, and on a protorendzina soil collected from carboniferous limestone ledges where the soil depth seldom exceeded 5 cm. Both soils were sieved and placed in plastic pots. Seeds were germinated on moistened filter paper and seedlings planted one per pot. The plants were grown in a glass-house with additional illumination from Phillips 'Daylight' fluorescent tubes. The soils were moistened daily with glass-distilled water. Plants were harvested at intervals over a period of 6 weeks. Chlorophyll was estimated in an 80 per cent acetone extract of the fresh leaves from the optical densities at wave-lengths 645 and 663 mμ (ref. 1).

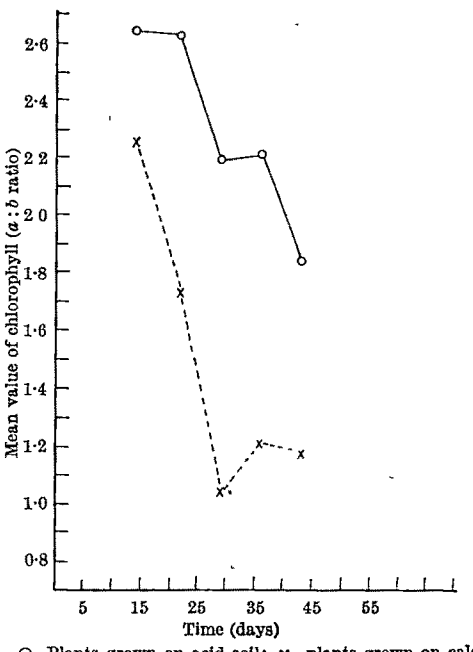

Fig. 1. O, Plants grown on acid soil; ×, plants grown on calcareous soil

In the first fortnight of growth there was a suggestion of a lower chlorophyll *a* : *b* ratio in the plants on the calcareous soil (Fig. 1). This became statistically significant after three weeks, due mainly to a lower chlorophyll *a* content (Fig. 2). Plants on both soils showed a fall in the chlorophyll *a* : *b* ratio with time but it is thought likely that the fall in plants growing on the acid soil represents an ontogenetic drift. By the end of the experiment there was a marked discrepancy in the growth of the plants in the two treatments. Plants grown on the acid soil had tillered several times while those grown on the calcareous soil had not. Chlorophyll *b* contents were similar in both treatments and showed no appreciable fall with time.

Some authors have implicated the bicarbonate ion as a causal agent in lime-induced chlorosis[2–4]. It was, therefore, decided to see if the bicarbonate ion had a similar effect on the chlorophyll content as did the calcareous soil. Seedlings were grown in water culture using the nutrient solution of Arnon and Hoagland[5] at one-fifth strength. Twenty m.equiv./l. sodium bicarbonate was added to one series of nutrient solutions and a similar concentration of sodium sulphate to the other. The *p*H's of the nutrient solutions were adjusted to *p*H 7·5. After 14 days, during which time the solutions were changed every 3 days, the plants were harvested and the chlorophyll contents determined. Chlorophyll *a* : *b* ratios were significantly lower in the bicarbonate treatment due mainly to a lower chlorophyll *a* content; for 18 deg. of freedom $t = 3{\cdot}83097$, $P = < 0{\cdot}01 > 0{\cdot}001$ (Table 1).

Table 1

	Chlorophyll *a**	Chlorophyll *b**	Chlorophyll *a* : *b*
Arnon/5 + 20 m.equiv./l. Na_2SO_4	1·04	0 53	1·97
Arnon/5 + 20 m.equiv./l. $NaHCO_3$	0·82	0·50	1 64

* Mean values in mg/g fresh weight.

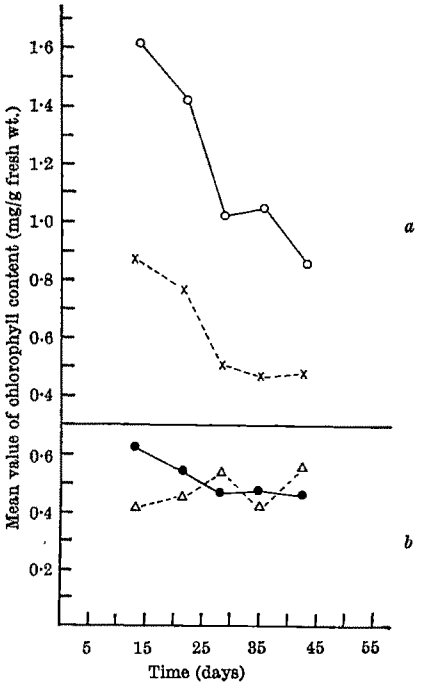

Fig. 2. *a*, Chlorophyll *a*. ○, Acid soil; ×, calcareous soil. *b*, Chlorophyll *b*. ●, Acid soil; △, calcareous soil

Thus the addition of bicarbonate ions to the nutrient solution caused a change in the chlorophyll *a* : *b* ratios in the same direction and in a similar manner to growth on a calcareous soil. Whether the bicarbonate ion is a direct cause of this change or whether it affects the availability and absorption of other ions from the nutrient solution was not determined. Plants grown on the calcareous soil developed a temporary purpling of the leaves symptomatic of phosphorus deficiency. No such purpling was recorded in growth on water culture. The work of Wallihan[6], showing that bicarbonate ions inhibit the uptake of ^{59}Fe by citrus roots, suggests that the present effects could be the consequence of a similar process. It is not possible to say whether the observed chlorophyll irregularities were produced by similar processes in the soil and in the water culture.

ENTOMOLOGY

Effect of Zinc Ions on Mitosis in Wing Anlagen of *Ephestia kühniella* Z. *in vitro*

Some heavy metal ions, particularly zinc, have been shown to imitate the cytological effects of the insect molting hormone, 'ecdyson', in explanted dipteran salivary glands[1]. The use of such substances as hormone imitators would greatly facilitate research by providing readily available substitutes for the actual hormone. It is therefore worth while investigating this possibility further. This report describes the action of zinc on mitosis in cells of wing anlagen of meal moth larvae, *Ephestia kühniella* Z.

Experimental animals were mass-reared at 25° C until the seventh day of the last larval instar according to previously described methods[2,3]. The larvae were then anaesthetized with ether, immersed in 0·9 per cent sodium chloride, and the hind wing buds removed from the metathorax through dorsal and lateral incisions in the body wall.

Fixation and dyeing were achieved simultaneously by immersing the anlagen for 2 h in a solution of four parts aqueous aceto-carmine, three parts 94 per cent ethyl alcohol, and one part glacial acetic acid. The aceto-carmine was prepared by adding 1 g carmine to 100 ml. distilled water and 100 ml. glacial acetic acid, boiling the solution for 3 h and then filtering. The anlagen were mounted in a mixture of 1 : 1 'Celodal' (Merck A.G., Darmstadt) and glacial acetic acid. Mitoses were counted under a magnification of 500 times.

Test solutions were made by dissolving Merck analytical grade zinc chloride containing 1·2 per cent zinc oxide in distilled water and filtering before use. All solutions were brought to approximately the same molarity (0·15 M) by adding appropriate amounts of sodium chloride. Experiments were conducted either at room temperature (19°–22° C) or at a constant temperature of 25° C. Duplicate experiments under both conditions yielded nearly identical results.

The numbers of pro-, meta-, and ana-phases counted on the upper sides of right imaginal disks after immersion for various times in solutions of sodium chloride and zinc chloride are shown in Fig. 1. The left anlagen were fixed immediately after dissection and thus served as paired controls for the right disks. Preliminary tests showed that statistically equal numbers of mitoses normally occurred in left and right anlagen. Each point on the graphs in Fig. 1 represents the mean of five to twelve anlagen.

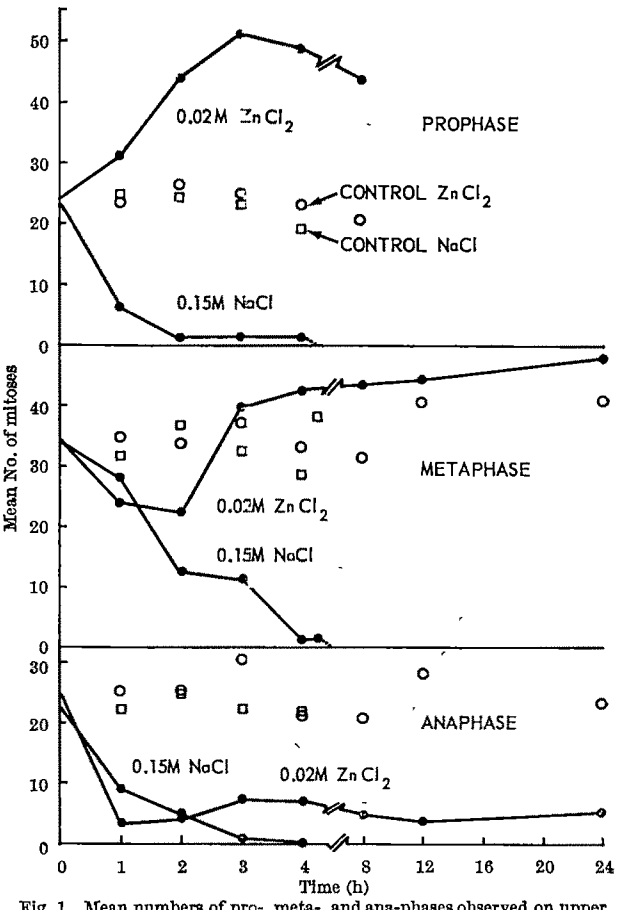

Fig. 1. Mean numbers of pro-, meta-, and ana-phases observed on upper sides of anlagen submerged for various times in 0·15 M sodium chloride and 0·02 M zinc chloride solutions. Control anlagen for experiments with sodium chloride (□) and zinc chloride (○) fixed immediately after dissection

Prophase nuclei disappeared rapidly in 0·15 M sodium chloride and were rare after 2 h. Conversely, the number of prophases in anlagen in 0·02 M zinc chloride rose steeply to a peak after 3 h when twice as many were present as in the controls. The numbers of metaphases in anlagen in both 0·15 M sodium chloride and 0·02 M zinc chloride decreased similarly during the first hour. In sodium chloride this decline continued until nearly all metaphases had disappeared after 4–5 h. However, in 0·02 M zinc chloride the reduction in number of metaphases ceased after 1–2 h and afterwards rose sharply to a level slightly above that of the controls. A *t*-test for difference between paired samples showed that the numbers of metaphases in anlagen after 1 and 2 h in 0·02 M zinc chloride were significantly smaller than in the controls and significantly greater from 3 to 24 h. Anaphases decreased quickly at first in 0·02 M zinc chloride and then remained at a relatively constant low level. In 0·15 M sodium chloride no anaphases occurred at all after 4 h. Mitosis may have been stimulated by the Zn^{++} at a concentration of 0·02 M zinc chloride and continued to be initiated for 3 h. A stimulation is not definitely proved, however. It may be merely that Zn^{++} initially supports continuing mitosis, somehow temporarily improving the poor sodium chloride medium, although other work[4] tends to indicate that a stimulation may be involved. Whatever the exact nature of the effect, it is accompanied by a blockage of mitosis in the metaphase due to disruptions of the mitotic figure by the Zn^{++}. Characteristic signs of zinc poisoning, such as shortening, clumping, and distortion of the mitotic figure, became increasingly obvious in anlagen after extended immersion in 0·02 M zinc chloride.

The increase in mitosis did not occur in anlagen in either 0·01 M or 0·1 M zinc chloride. At the higher concentration both metaphases and anaphases were blocked and their numbers remained the same as in the control anlagen. At lower concentrations only the metaphases were blocked.

Mitosis was favoured by Zn^{++} only when anlagen were exposed to the solution almost immediately after dissection. One hour later the cells had become incompetent to react to the Zn^{++}. This condition may be analogous to the irreversible 'rejuvenation' referred to by Kroeger[1], an unspecific response of the cell to mechanical or chemical wounding causing it to revert to a more juvenile stage of development.

How zinc may promote mitosis is not exactly known. It has been shown to stimulate RNA and protein synthesis in *Rhizopus nigricans*[4]. Accumulation of zinc on the chromosomes in prophase and its subsequent release in anaphase has also been recorded[5] and may be associated with the acquisition by chromosomes of ribonucleoprotein at prophase and its ensuing release at anaphase[6]. A structural function of zinc is suggested similar to the role of magnesium and other divalent metals in preserving the structural integrity of ribonucleoprotein particles and thus influencing the rate of protein synthesis[7].

This work was supported by a fellowship from the Alexander von Humboldt-Stiftung, Bad Godesberg, Germany, and was completed while I was a guest at the Institute for Developmental Physiology, University of Cologne, Cologne, Germany. I thank Prof. C. Harte, director of the Institute, for her hospitality, and Prof. L. Stange and Prof. H. J. Pohley for their advice.

MICROBIOLOGY

Effect of Antibiotics on Some Rumen and Intestinal Bacteria

Antibiotics have been for some time added to ruminant feeds to increase the weight gains of the animals and they have also been advocated as remedies for bloat[1]. Some workers have also used antibiotics as additions to *in vitro* experiments on the basis that this would suppress the activities of the bacteria in mixed rumen contents and that residual enzyme activity would be caused by protozoa. (See, for example, ref. 2.) Antibiotics have also been used regularly to suppress bacterial growths in the *in vitro* culture of protozoa[3]. Little has, however, been done to test the susceptibility to antibiotics of defined strains of rumen bacteria, especially the strictly anaerobic types. Such anaerobic types have also been found in the intestines of ruminants and non-ruminants.

In the course of work on the effects of antibiotics on rumen function, we have screened a number of antibiotics for their action against some representative rumen and intestinal bacteria. The results are presented here. The strains of *Selenomonas ruminantium*, *Lactobacillus bifidus*, *Butyribibrio* sp. *Bacteroides amylophilus*, and an anaerobic lipolytic bacterium 5*S*[4], were isolated from the sheep rumen. The strain of *Ruminococcus albus* came from an air sample from a cowshed. *Veillonella gazogenes* was from the bovine rumen, while *Lactobacillus fermenti* and *Peptostreptococcus elsdenii* were taken from the rumens of young calves and *Streptococcus bovis* from the rumen of a young calf which had had aureomycin included in its feed. The strain of *Escherichia coli* was isolated from the intestinal tract of a four-day old guinea-pig. With the exception of the lipolytic bacterium, the organisms were grown in a medium the constituents of which were: mineral solutions *a* and *b*[4], 15 ml. each; centrifuged sheep rumen fluid, 30 ml.; Bacto yeast extract, 0·2 g; resazurin, 0·1 ml. of 0·1 per cent solution; sodium bicarbonate, 0·6 g; cysteine hydrochloride, 0·05 g; glucose, cellobiose and maltose, 0·1 g each; 70 per cent sodium lactate solution, 0·125 ml.; water to 100 ml. The medium for the lipolytic bacterium had 0·1 ml. glycerol instead of the sugars and lactate.

The media were prepared, dispensed and incubated under oxygen-free carbon dioxide in a manner similar to that previously described for such media[4]. The addition of the various sugars to the basal medium, and the presence of rumen fluid, were necessary to ensure that all the organisms would grow and that they would then be tested under similar conditions. The various organisms were kept on slopes of the foregoing media solidified by the addition of agar (2 per cent w/v), transferred from the stock slopes to tubes of liquid media, as above, and incubated for 24 h at 38° C. Slopes of the media of maximum surface area were prepared in 6 in. × 0·5 in. test-tubes under carbon dioxide by setting 4 ml. of medium in the tube at a small angle to the horizontal, and these slopes were inoculated at the bottom of the slope with two drops (0·05 ml.) of the 24 h cultures. The inoculum was spread over the surface of the slope with a wire spreader in a standard manner, all the manipulations being done under a stream of carbon dioxide. The slopes were then stored at room temperature for 15 min and then a sterile disk of filter paper containing antibiotic was placed in the centre of the slope, again under carbon dioxide, and the tube stoppered. The slopes were incubated upright at 38° C for 3 days and the growth noted on each day. Control slopes without antibiotic showed a uniform growth after 24 h. Antibiotic inhibition showed as the familiar circle of clear medium around the disk. The 'Tylosin' was tested in the form of factory-prepared disks containing 30 μg 'Tylosin' phosphate ('Tylan'); the other antibiotics were prepared as filter-sterilized solutions of concentration 1 mg/ml. and the disks used were of

The antibiotic was added to a paper disk on the slope. *5S* indicates a strain of unclassified anaerobic lipolytic bacterium; +, inhibition of growth around disk; −, no inhibition. +−, small zone of lighter growth than rest of slope, no complete inhibition; * indicates that 'resistant' colonies grew in this inhibition zone after 1 or 2 days.

Whatman No. 1 filter paper, 6·5 mm in diameter and containing approximately 0·01 ml. of solution.

A positive result is shown in Table 1 whenever a clear zone was found, but the zones of inhibition varied in size with different antibiotics and organisms. The results support the use of chloramphenicol as an agent for suppressing the growth of bacteria in cultures of rumen protozoa and give a guide to the effects of other antibiotics on rumen function. The action of penicillin on strain *5S* could account for the marked reduction in lipase activity noted by Wright[2] in the rumen of a cow to which penicillin had been given orally. Wright also noted that streptomycin had no effect on lipase activity. In a number of cases, one or more colonies of the test organism appeared in the inhibition zone after more than one day of incubation, and this was especially noticeable in the case of penicillin *G*. Further work with liquid cultures showed that penicillin *G*, in concentrations up to 5 μg/ml., was completely destroyed in this medium after incubation for two days, and that higher concentrations lost a proportion of their activity. Growth of bacteria could appear at random in tubes of the liquid penicillin containing medium two days after inoculation. However, when sub-cultures were made from these tubes, or from apparently resistant colonies on agar slopes, into media containing penicillin, it was apparent that the organisms were not truly resistant to the antibiotic. The initial growth must have been due to chance survival of some of the inoculum until the penicillin concentration had been reduced below the inhibitory level.

We are grateful to T. H. Blackburn and S. O. Mann for some of the organisms used in this survey. We would also like to thank the Wellcome Foundation for a maintenance grant to one of us (I. E. A.), and the companies which provided the antibiotic samples.

Adaptation of Bacteria from One Type of Hydrocarbon to Another

THE ease with which various bacteria assimilate hydrocarbons is known to vary with the structure of the hydrocarbon[1]. As part of an investigation of the fermentation of hydrocarbon material by bacteria we have investigated the relative rates of bacterial growth on liquid hydrocarbons of different structures. About thirty different kinds of bacteria, including *Pseudomonas fluorescens* and several species of *Corynebacterium*, have been isolated from soil samples taken from industrial oil and chemical spillage areas and from garden soils. The most rapid growth of fresh isolates from soil samples occurred with the normal paraffins $C_8 - C_{18}$, but growth on normal $C_5 - C_8$ hydrocarbons was much less rapid. This may be explained by the known toxicity of the lower alkanes to bacteria because of their lipid solvent properties. The hydrocarbons listed as follows are classified in decreasing order of ability to support bacterial growth:

Class 1. *n*-Paraffins (C_8–C_{18}).

Class 2. Branched chain alkanes (3-methylheptane; 2,2,4-trimethylpentane; pentamethylheptane; 2,2,4,4,6,-8,8,-heptamethylnonane; propylene tetramer).

Class 3. *n*-Paraffins (C_5–C_8).

Class 4. Cyclic hydrocarbons (*cyclo*hexane, methyl-*cyclo*hexane, decalin, benzene, *m*-xylene).

Bacteria isolated with the aforementioned hydrocarbons as sole carbon source were able to adapt from one hydrocarbon to another. However, there was a marked variation in the ease with which the different hydrocarbons were utilized by the same organism. Micro-organisms isolated on hydrocarbons low in the foregoing classification rapidly adapt and then grow well on a hydrocarbon higher in the list, but adaptation in the reverse sense did not apply. A typical set of experimental results is given in Table 1.

Table 1. BACTERIAL GROWTH AFTER ADAPTATION TO NEW CARBON SOURCES

Bacterial strain	Hydrocarbon used for isolation: Class	Substance	Hydrocarbon used to test adaptability: Class 1 Decane	Class 2 2,2,4-Trimethylpentane	Class 3 Pentane	Class 4 *cyclo*hexane
HD	1	Dodecane	+	+	−	−
CD	1	Dodecane	++	+	−	−
Q i/o	2	2,2,4-Trimethylpentane	++	+++	−	−
M1 i/o	2	2,2,4-Trimethylpentane	+++	++	−	−
SP	3	Pentane	+++	++	++	+
LP	3	Pentane	+++	+	+	−
Q c/h	4	*Cyclo*hexane	+++	+	+	++
T c/h	4	*Cyclo*hexane	++	+	+	++

+++, Between 5×10^8 and 5×10^9 cells/ml.
++, Between 5×10^7 and 5×10^8 cells/ml.
+, Between 5×10^6 and 5×10^7 cells/ml.
−, Less than 5×10^6 cells/ml.

All bacteria in Table 1 except *HD* are species of *Corynebacterium; HD* is a variety of *Pseudomonas fluorescens*. The cultures were incubated in static conical flasks containing 100 ml. of mineral salt solution (1·6 g KH_2PO_4; 0·8 g Na_2HPO_4; 0·5 g $MgSO_4.7H_2O$; 0·5 g NaCl; 5 g NH_4Cl in 1 l. of distilled water) and 2 ml. hydrocarbon at

30° C for 1 week. The growth was estimated as total cell count using a Thoma chamber.

I am grateful to Dr. D. S. Davies for his interest.

VIROLOGY

Small-plaque and Large-plaque Variants of Papova Virus SV_{40}

Plaque size constitutes an important genetic characteristic of many viruses, including polyoma virus[1–3]. We have shown the existence of large-plaque (*LP*) and small-plaque (*SP*) variants for another Papova virus—SV_{40}.

The plaque-forming ability of nine strains of SV_{40} was investigated: *A*-426 (ref. 4), 128, 129, 130, 131 (all were isolated from *M. rhesus* kidney tissue cultures and kindly supplied by Dr. Deichman), 261 (isolated by Dr. Deichman from a hamster tumour induced by SV_{40}), *MR*-1, *MR*-2 (isolated in this laboratory from *M. rhesus* kidney tissue culture) and *I*-1 (isolated from hamster tumour formed by SV_{40}). All viruses were propagated in green monkey kidney tissue cultures. Plaques formed by these different virus strains were compared by inoculating green monkey kidney cell culture in 50-ml. bottles with about 50 p.f.u. in 0·1–0·2 ml. After 2 h adsorption at room temperature, the cell monolayer was overlaid with nutrient agar using a modification of the technique of Stinebaugh and Melnick[5] ('Difco' agar, 1·5 per cent; ten-fold Earle's solution, 10·0 per cent; skimmed milk, 10·0 per cent; calf serum, 1·0 per cent; sodium bicarbonate, 0·4 per cent; neutral red, 0·0017 per cent; in de-ionized water). The infected tissue cultures were incubated at 37° C. The timing of plaque appearance was followed and their size measured on a given day of incubation.

The diameters of the plaques formed by two virus strains on the fourteenth day after inoculation are shown in Table 1 (all plaques formed in the bottles were measured). Though great variability of plaque size is characteristic of SV_{40}, strain *A*-426 predominatingly formed larger plaques, while strain 128 formed smaller ones. The difference could easily be seen without special measurement. Moreover, the plaques of strain *A*-426 appeared 2–7 days earlier than did those of strain 128 (the exact interval varied for different batches of tissue culture cells).

Table 1. Comparison of the Size of Plaques formed by Two SV_{40} Strains on the Fourteenth Day after Tissue Culture Inoculation

Strain	No. of plaques measured	Percentage of plaques at the given diameters (mm)						Mean diameter (mm)
		< 0·5	0·5–0·7	0·8–1·0	1·1–1·5	1·6–2·0	> 2·0	
A–426	143	0·7	24·4	28·0	21·7	20·3	4·9	1·1
128	164	28·6	58·0	10·4	2·4	0·6	0·0	0·5

Investigation of the other seven strains of SV_{40} showed that strain 130 was identical with strain 128. This was so with respect both to the rapidity of plaque formation and the size of plaques formed (these strains were therefore termed *SP* strains); the remaining six strains were identical with strain *A*-426 (*LP* strains). Differences between *SP* and *LP* strains were constantly found in repeated assays, though they varied in degree.

It is possible that these differences between the two types of strains may be associated with the contamination of *SP* strains by a high concentration of a latent interfering virus. Simultaneous inoculation of tissue culture with equal doses of strains *A*-426 and 128 had, however, no effect on the time of appearance or on the size of plaques induced by the former (*LP*) strain. Differences in plaque formation cannot, therefore, be accounted for by contamination by an interfering agent.

All the strains examined were cloned, and the cloned lines were passed four times in green monkey kidney cell culture. All cloned lines were identical in plaque-forming capacity with their parent strains.

To establish that plaque size was a genetic characteristic of virus particles, we investigated clones obtained from small and large plaques of *SP* and *LP* strains (Table 2). Whatever the size of the plaque used for cloning, the resulting clones did not differ from their parent strains. Plaque size was variable within each strain, but could not be accounted for by the viral genome.

Table 2. Characteristics of Plaque Formation by Cloned Lines obtained from Large and Small Plaques of Large-plaque (*LP*) and Small-plaque (*SP*) Strains of SV_{40}

Strain	Original characteristic	Diameter of the plaque cloned (mm)	Number of clones	Clone characteristics*
A–426	*LP*	0·3–0·5	3	*LP*
		2·0–3·0	3	*LP*
129	*LP*	0·3–0·5	3	*LP*
		2·0–3·0	2	*LP*
128	*SP*	0·3–0·5	3	*SP*
		1·0–1·5	2	*SP*
130	*SP*	0·3–1·5	7	*SP*

* Rate of appearance and the size of plaques were determined by comparison with those of *A*-426 strain.

According to preliminary data, *SP* and *LP* strains do not differ in their sensitivity to agar polysaccharide and do not adsorb on to cells at different rates—as has been shown for polyoma virus variants[6]. Both *SP* and *LP* strains of SV_{40} produced transformation in cultures of human and rat embryo fibroblasts[7].

Further investigations should show whether it is possible to isolate *SP* variants from *LP* strain population and *LP* variants from *SP* strain population.

CYTOLOGY

Microtubules in the Cytoplasm of Mammalian Platelets

Of late, and with increasing frequency, microtubules have been recognized as a cytoplasmic component in cells examined in thin section by electron microscopy (see review by Slautterback[1]). Their presence in the cytoplasm of human, guinea-pig and mouse platelets is recorded in this communication.

Using siliconized hypodermic needles and glassware and 3·8 per cent trisodium citrate (*p*H 7·4) as an anticoagulant, blood was collected from animals of both sexes. It was taken from the antecubital vein of eleven humans and, after an ether anaesthetic, by cardiac puncture from six guinea-pigs and from the retro-orbital sinus of eighty-four mice. That from six or twelve mice was pooled for subsequent processing. Aliquots of platelet-rich plasma, which had been separated from the blood by centrifugation, were fixed 2 h in 5 per cent glutaraldehyde[2] made up in Sörensen's phosphate buffer (*p*H 7·4), and were then subjected to further centrifugation. Platelet pellets so obtained were washed in the phosphate buffer, post-fixed 2 h in osmium tetroxide containing sucrose[3] (*p*H 7·4), then washed in water, dehydrated in ethanol, and embedded in 'Araldite'. Grey to pale gold thin sections

were cut with a glass knife. They were stained, first in a saturated solution of uranyl acetate in 70 per cent alcohol and then either with lead citrate[4] or with lead hydroxide[5] and examined in a Siemens 'Elmiskop 1' electron microscope.

Microtubules were observed approximately 500 Å deep to the plasma membrane in platelets from the three species. They were defined by an electron-dense wall some 70 Å thick that enclosed a less dense core and had an overall diameter of about 250 Å. The wall had smooth inner and outer surfaces and did not have the features of a unit membrane[6].

Their position in the cytoplasm was related to the shape of the sectioned platelet. Thus, in oval or elliptical sections, microtubules were found usually at opposite ends of the platelet profile. They were present either as groups cut in cross-section, or as five or six roughly parallel microtubules cut in longitudinal sections of varying length and, in either instance, were placed about 100 Å apart (Fig. 1). Some were surrounded by a zone of ground substance that was less electron dense than elsewhere, perhaps indicating a particular composition.

The number of microtubules in groups cut in cross-section varied from one end of an individual platelet to the other and also from platelet to platelet. On average, thirteen were present in groups in human and mouse platelets and ten in guinea-pig platelets. However, for reasons discussed by Fawcett and Witebsky[7] in relation to microtubule enumeration in nucleated erythrocytes, the accuracy of the counts is probably low. Groups of microtubules cut in cross-section were seen occasionally at sites other than the poles.

Guinea-pig platelets were often remarkably elongate. In these, several parallel microtubules cut in longitudinal section, or discontinuous fragments of single tubules passed from one pole to the other. Short segments of single tubules were also seen in the central zone of platelets that had transected tubules at either end.

Several parallel tubules, running deep to the plasma membrane and describing arcs of varying length, were present in round sections of platelets from all animals. Single tubules, which passed either towards or from those in the peripheral position, either followed a convoluted course in the central area of the section or crossed the diameter (Fig. 2).

Uncommonly, sectioned platelets had a squarish outline. In these, microtubules cut either in cross-section or longitudinal section could be seen in any corner.

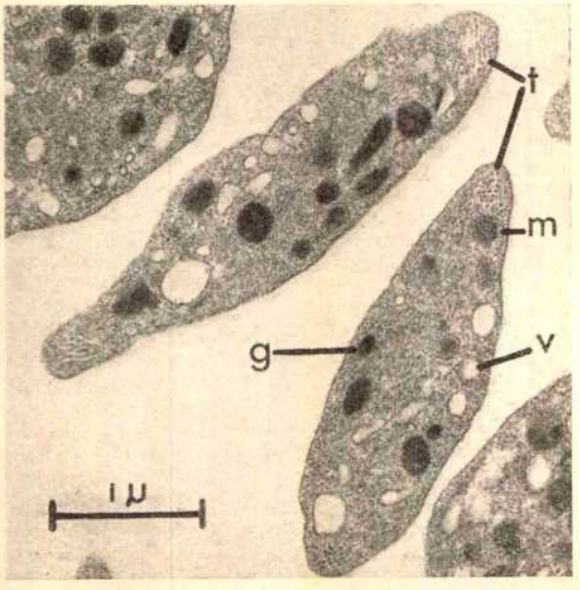

Fig. 1. Microtubules (*t*) present in cross- or longitudinal section at either pole of human platelets. Dense granules (*g*), vesicles (*v*), and mitochondria (*m*), also present in cytoplasm. (× 20,000)

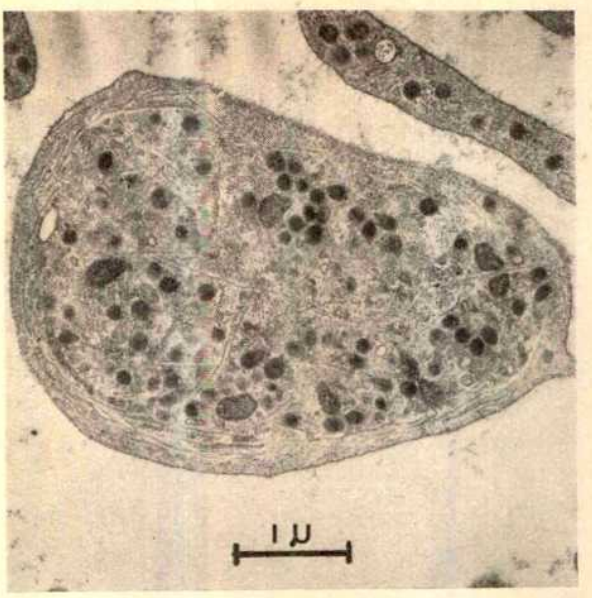

Fig. 2. Several roughly parallel microtubules describe a circumferential course approximately 500 Å deep to the plasma membrane of a guinea-pig platelet. Other single tubules have a radial arrangement. (× 15,000)

Human and mouse platelets showed occasional spikes or pseudopod-like structures projecting from their otherwise smoothly contoured outline. In some instances, several parallel microtubules cut in longitudinal section passed from either side of the platelet into the base of the spike, intermingled and continued towards its tip. It is not certain whether the two groups of tubules overlapped or fused. Furthermore, since it was usual for the tip of the spike to be out of the plane of section, it was not clear whether the two groups formed a loop at the apex, or came to a point like the walls of a tepee, or came into contact with the plasma membrane. Contact between microtubules and plasma membrane was not apparent elsewhere.

These observations, coupled with those made on rabbit platelets[8], suggest that microtubules may be present in the cytoplasm of all mammalian platelets. It is of interest that similar structures have been described forming an annular, paranuclear band in thrombocytes of the toadfish *Opsanus tau*[7].

Furthermore, the findings suggest that the anatomical arrangement of microtubules in mammalian platelets is in the form of a marginal band containing several tubules, with other single tubules running a radial course. Support for this conclusion is gained by the presence of circumferential and radial fibres in the hyaloplasm of platelets spread on films and examined with an electron microscope[9,10]; the difference in the recorded dimensions of fibres and microtubules being explained by the different methods of preparation used[11]. Added support is gained by comparison with analogous observations made on marginal bands found in nucleated erythrocytes from non-mammalian vertebrates[7,11].

The function of microtubules has still to be determined[1,7]. Perhaps their action on the plasma membrane causes spike formation. Alternatively, their extension into these cytoplasmic projections may be a secondary phenomenon. Investigation of microtubule morphology during the action of agents known to cause platelet aggregation[12] may give insight into their function and establish their role in thrombus formation.

I am indebted to Dr. E. DeSalis, Commonwealth Health Laboratory, Canberra, A.C.T., for human blood samples, and to Miss N. Carroll for technical assistance.

Note added in proof. Since submitting this communication, G. B. Haydon and D. A. Taylor (*J. Cell. Biol.*, 26, 673; 1965) have reported finding microtubules in hamster platelets, and O. Behnke (*J. Ultrastruct. Res.*, 13, 469;

1965) has described microtubules forming a marginal bundle in human and rat thrombocytes.

AGRICULTURE

Field Responses of Cereals to Molybdenum

Reports of field occurrences of molybdenum deficiency in small-grained cereals are rare. Fricke[1] in Tasmania showed that the 'blue chaff' disease of oats could be cured by applying molybdenum. Lobb[2] and Fitzgerald[3] in New Zealand, and Mulder[4] in The Netherlands, have reported responses with field grown oats to molybdenum. Lobb[2] and Mulder[4] have also obtained field responses with wheat to molybdenum. It has been found that large areas of Australian soils are deficient in molybdenum that can be used for nitrogen fixation by Leguminosae, and for growth by Cruciferae, Compositae, Cucurbitaceae, Solanaceae and Linaceae[5]. The only field responses in the Gramineae in Australia are those reported by Fricke[1] with oats, and Noonan[6] with maize. It has frequently been demonstrated, for example by Johnson *et al.*[7], that members of Gramineae are relatively tolerant of low supplies of molybdenum and that molybdenum deficiency in cereals only occurs in extreme conditions of molybdenum deficiency.

This communication reports field responses to molybdenum by wheat and by oats in mainland Australia. The responses occurred in a region of the West Australian wheatbelt which receives 12–13 in. of rainfall annually. The soils concerned are sandy and lateritic podsols which are extremely deficient in native phosphate, deficient in nitrogen and often deficient in copper and/or zinc. Plant responses to molybdenum in this region have not previously been reported.

Ballidu oats were planted on June 2, 1962, east of Gutha. Observed in early August, the plants on the plots which were not treated with molybdenum appeared a slightly paler green than those on the plots treated with molybdenum, but no other differences were noticed. The results for grain yield are shown in Table 1 (Exp. 1). Highly significant increases in yields resulted from the application of molybdenum, and these increases were magnified by the application of 1 cwt. of ammonium sulphate/acre.

The wheat used in Exp. 2 was sown in 1960, east of Gutha. Molybdenum treatments caused no visible differences: grain yields are shown in Table 1. Application of molybdenum resulted in markedly increased yields only with ammonium sulphate (1 cwt./acre).

A further experiment with Gabo wheat planted on June 2, 1962, immediately adjacent to the oat plots, produced grain yields as shown in Table 1 (Exp. 3). Molybdenum markedly increased the yields, and the effect was again enhanced by treatment with 1 cwt. ammonium sulphate/acre. As with the oats, the only visible difference was a slight chlorosis of those wheat plants on plots which were not treated with molybdenum when compared with plants on plots which received molybdenum.

Table 1. Effect of Molybdenum on Oat and Wheat Grain Yields* at Gutha

	Exp. 1, Ballidu oats, Gutha, 1962	Exp. 2, Gabo wheat, Gutha, 1960	Exp. 3, Gabo wheat, Gutha, 1962
Superphosphate (150 lb./acre)	15·2	18·0	9·4
Superphosphate (150 lb./acre) + molybdenum trioxide (2 oz./acre)	17·2	17·8	11·5
Superphosphate (150 lb./acre) + ammonium sulphate (112 lb./acre)	12·2	18·8	11·9
Superphosphate (150 lb./acre) + ammonium sulphate (112 lb./acre) + molybdenum trioxide (2 oz./acre)	17·8	22·4	15·3
	Mo signif. at $P < 0·001$. S/A × Mo significant at $P < 0·05$. S/A effect N.S.	Mo signif. at $P < 0·05$. S/A significant at $P < 0·001$. S/A × Mo significant at $P < 0·001$	Mo signif. at $P < 0·001$. S/A × Mo interaction N.S.

* Yields in bushels/acre: 40 lb. to the bushel for oats; 60 lb. to the bushel for wheat.

Table 2. Effect of Molybdenum on Vegetative and Grain Yield of Wheat at Bodallin

	Exp. 4, Bencubbin wheat, Bodallin, 1964	
	Vegetative yield at 11 weeks. Dry matter in lb./acre	Grain yield (bushels/acre)
Superphosphate (180 lb./acre)	91·4	7·2
Superphosphate (180 lb./acre) + urea (24 lb./acre)	122·1	9·1
Superphosphate (180 lb./acre) + urea (50 lb./acre)	137·8	7·3
Superphosphate (180 lb./acre) + urea (76 lb./acre)	152·0	6·7
Superphosphate (180 lb./acre) + molybdenum trioxide (2 oz./acre)	119·5	9·6
Superphosphate (180 lb./acre) + urea (24 lb./acre) + molybdenum trioxide (2 oz./acre)	169·9	10·3
Superphosphate (180 lb./acre) + urea (50 lb./acre) + molybdenum trioxide (2 oz./acre)	176·3	9·7
Superphosphate (180 lb./acre) + urea (76 lb./acre) + molybdenum trioxide (2 oz./acre)	244·0	10·9
	Mo significant at $P < 0·001$; urea linear significant at $P < 0·001$; Mo urea linear significant at $P < 0·05$	Mo significant at $P < 0·001$

In 1964, at Bodallin, 180 miles south-east of the Gutha sites, striking responses in vegetative growth and grain yield of Bencubbin wheat resulted from the application of molybdenum. Within 5 weeks of seeding, differences in growth and colour due to molybdenum treatments were noticeable. Vegetative yields at 11 weeks after seeding are shown in Table 2.

Molybdenum application advanced maturity by approximately 10 days. Whiteheads barren of grain were abundant and scattered throughout those plots which were not treated with molybdenum. Grain yields are shown in Table 2.

That cereals respond so markedly to the application of molybdenum indicates that these soils contain little molybdenum that can be made available to plants. Numerous and widespread responses with pasture legumes in experiments carried out in 1964 have shown that extensive areas of molybdenum deficiency exist in the sheep and wheat growing area of South Western Australia.

This work was carried out with the co-operation of R. J. Doyle, R. J. Parkin, and J. A. C. Smith, advisers to the Wheat and Sheep Division, West Australian Department of Agriculture.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 7

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 5.15 p.m.—Prof. Theodor Bücher (University of Munich): "Dynamics of Liver Metabolism" (further lecture on March 9).*

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. P. J. N. Norris: "An Introduction to Silicon Controlled Rectifiers".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. H. M. Finniston: "Experimenting in Experiments".

Tuesday, March 8

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 2.30 p.m.—Symposium on "Mathematics in Economics". Speakers: Prof. J. R. N. Stone, C.B.E., Dr. F. H. Hahn and Prof. J. D. Sargan.

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. R. E. Rowe and Mr. G. D. Base: "Model Analysis and Testing as a Design Tool".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (joint meeting with the Society of Instrument Technology, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. I. R. Young, Mr. A. T. Keefe and Mr. G. Moss: "A New Approach to Measurement and Data Transmission for Process Control Systems".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. W. S. Campbell: "Applications of Latex in Industry". 7 p.m.—Panel Discussion on "Natural and Synthetic Latices v. Polyurethane in Foam Applications".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. Blaauw (University of Groningen): "Distribution and State of Motion of the Interstellar Gas in the Solar Neighbourhood".*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Prof. Holger Arbman: "Early German Animal Style in the 5th–7th Centuries A.D.—III. The Late Vendel Styles in Scandinavia and Its Relationships with the Continent and the British Isles".*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. R. J. Allwood and Mr. C. C. Norville: "The Analysis by Computer of a Motor Car Underbody Structure".

Wednesday, March 9

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, London, S.W.7), at 4 p.m.—Annual General Meeting, followed by Dr. G. H. Byford: "The Measurement of Human Reactions to Environmental Changes".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. A. W. Bright and Dr. P. L. Secker: "Applications of Electrostatics".

SOCIETY OF INSTRUMENT TECHNOLOGY (in conjunction with the British Computer Society, at Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. R. G. Blake: "Use of a Digital Analogue Simulator"; Dr. L. J. Postle: "Analogue Computers and Chemical Plant Control System Design in Practice"; Dr. G. W. H. White: "The Calculation of Pole Zero Patterns for Process Control".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. Blaauw (University of Groningen): "Properties of the Youngest Stellar Population in the Solar Neighbourhood with special reference to the Problem of Star Formation".*

UNIVERSITY OF LONDON (in the Eugenics Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. M. Court Brown: "Essays in Human Cytogenetics: I. Autosomal Structural Heterozygosity".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p.m.—Prof. C. W. Oatley, O.B.E.: "The Scanning Electron Microscope and other Electron Probe Instruments".

SOCIETY FOR ANALYTICAL CHEMISTRY (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Annual General Meeting followed by Dr. J. T. Martin: "Chemical Crop Protection in Britain".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the College of Technology, Roe Green, Hatfield), at 7.30 p.m.—Dr. G. A. Williams: "Some Aspects of the Chemistry of Free Radicals".

Thursday, March 10

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Prof. S. V. Perry: "Biochemistry of Muscle".*

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. B. C. Browne: "Gravity Surveying at Sea".

INSTITUTION OF CIVIL ENGINEERS, TRANSPORTATION ENGINEERING GROUP (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Traffic Survey for Smaller Towns" introduced by Mr. A. E. Fieldhouse.

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "The Multi-Carrier Performance of Communication Satellite Repeaters", opened by Mr. W. L. Wright, Mr. K. U. Bolwell and Mr. P. N. Sargeaunt.

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "The Application of Static Reactive Power Devices to Transmission and Distribution Networks", opened by Dr. E. Friedlander and Mr. L. A. Harris.

UNIVERSITY OF LONDON (at Queen Mary College, Mile End Road, London, E.1), at 5.30 p.m.—Prof. R. W. van Bemmelen (University of Utrecht): "A New Model for the Earth's Geological Evolution".*

UNIVERSITY OF LONDON (in the Eugenics Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. M. Court Brown: "Essays in Human Cytogenetics: II. The *y* Chromosome".*

INSTITUTION OF MECHANICAL ENGINEERS, MANUFACTURE AND MANAGEMENT GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Implications of Metric Conversion".

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at the School of Pharmacy, Brunswick Square, London, W.C.1), at 6 p.m.—Dr. P. Kresse: "Inorganic Pigments in Building".

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (joint meeting with the Food Group, at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. F. J. Ley: "The Use of Ionizing Radiations in Food Preservation".

Thursday, March 10—Friday, March 11

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m. daily—Discussion Meeting on "Circular Dichroism—Electronic and Structural Principles", organized by Prof. R. S. Nyholm, F.R.S.

Friday, March 11

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Prof. P. B. Beeson: "Bacterial Endocarditis".*

UNIVERSITY OF LONDON (at the Royal Veterinary College, Royal College Street, London, N.W.1), at 5 p.m.—Dr. K. L. Blaxter: "Some Effects of the Climatic Environment of Farm Animals".*

UNIVERSITY OF LONDON (in the Eugenics Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. M. Court Brown: "Essays in Human Cytogenetics: III. Population Studies: The Part and the Whole".*

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir Lawrence Bragg, O.B.E., M.C., F.R.S.: "Reminiscences of Fifty Years Research".

Saturday, March 12

NUTRITION SOCIETY (at the Medical School, Guy's Hospital, St. Thomas's Street, London, S.E.1), at 10.15 a.m.—Symposium on "Nutrition and Physical Performance".

Monday, March 14

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. A. Waldron: "The Explanation of Some Fundamental Phenomena of Modern Physics using a Ballistic Theory of Light".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. G. S. C. Brown: "The Ten-Element Band-Pass Filter Section and Its Applications".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Sky Above, the Mud Below" (colour film).

Monday, March 14—Friday, March 18

OIL AND COLOUR CHEMISTS' ASSOCIATION (in the Great Hall of Alexandra Palace, London, N.22)—Eighteenth Technical Exhibition.*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

UNIVERSITY DEMONSTRATOR (with a good honours degree or the equivalent in an appropriate subject and preferably some research and/or teaching experience) IN PLANT PATHOLOGY—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (March 9).

SCIENTIFIC OFFICER (with a good honours degree in zoology or applied entomology, and preferably some postgraduate experience) to carry out laboratory and field studies on the behaviour and performance of insecticides in soil to improve efficiency—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (March 11).

SENIOR LECTURER/LECTURER (preferably with previous computer programming experience, either academic or industrial) IN THE COMPUTER UNIT, to be responsible for the operational side of the University's computing service to consist of an Elliott 4130 system—The Registrar, University of Warwick, Coventry, Warwickshire (March 11).

ASSISTANT LECTURER OR LECTURER IN ZOOLOGY—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (March 14).

READER OR SENIOR LECTURER IN SOLID STATE ELECTRONICS; and LECTURERS (2) (one in the field of control systems) IN ELECTRONICS—The Registrar, The University, Canterbury, Kent (March 14).

LECTURER OR ASSISTANT LECTURER (with a special interest in either plant physiology or genetics) IN THE DEPARTMENT OF BOTANY—The Deputy Secretary, The University, Southampton (March 18).

SECOND CHAIR IN PHYSICS (applicants should have specialized in either experimental metal physics or in microwave physics)—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (March 18).

CHAIR OF PHYSICAL OCEANOGRAPHY—The Deputy Secretary, The University, Southampton (March 25).

ASSISTANT (honours graduate) IN THE DEPARTMENT OF BOTANY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (March 31).

CHAIR OF METALLURGY—The Registrar, The University, Sheffield (March 31).

CHAIR OF PHYSICS—The Registrar, The University, Sheffield (March 31).

LECTURER/ASSISTANT LECTURER (with a degree in medicine or science with suitable teaching and research experience, and preferably with a special interest in enzymology or biophysical chemistry) IN BIOCHEMISTRY at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, March 31).

LECTURER/SENIOR LECTURER IN BIOLOGY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 31).

RESEARCH ASSISTANT (graduate, man or woman, with a special interest in plant physiology or plant biochemistry) IN BOTANY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (March 31).

SENIOR LECTURER or LECTURER IN PHARMACEUTICS; a SENIOR LECTURER or LECTURER IN PHARMACOGNOSY; a SENIOR LECTURER or LECTURER IN PHARMACEUTICAL CHEMISTRY; and SENIOR LECTURERS or LECTURERS (2) in PHARMACOLOGY at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (March 31).

THIRD CHAIR OF PHYSICS—The Registrar, The University, Sheffield (March 31).

UNIVERSITY ASSISTANT LECTURER IN PURE MATHEMATICS—The Secretary to the Appointments Committee of the Faculty of Mathematics, The University, Silver Street, Cambridge (March 31).

LECTURERS or ASSISTANT LECTURERS (3) IN THE DEPARTMENT OF CHEMICAL ENGINEERING—The Assistant Registrar (Science and Engineering), The University of Birmingham, Birmingham, 15, quoting Ref. CE (April 1).

LECTURER IN BIOCHEMISTRY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, April 13).

LECTURER (with a good honours degree in electrical engineering, and industrial and research experience in the field of telecommunications and electronics) IN ELECTRICAL ENGINEERING at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, April 15).

LECTURERS or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of North Wales, Bangor, North Wales (April 18).

CHAIR OF GEOGRAPHY at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Kuala Lumpur, April 30).

LECTURER or ASSISTANT LECTURER (with a good honours degree, experience in modern semiconductor circuit design, and preferably an interest in communications engineering) IN ELECTRICAL ENGINEERING—The Secretary, The University, Edinburgh (April 30).

PROFESSOR OF GEOLOGY—The Registrar, University Registry, Oxford (April 30).

SECOND CHAIR OF ELECTRICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (April 30).

ASSISTANT PROFESSOR IN ANATOMY—The Chairman of the Department of Anatomy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

CHAIR OF OPHTHALMIC OPTICS AND HEAD OF THE DEPARTMENT—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref. OOD.

DEVELOPMENT ENGINEER IN THE GEOPHYSICS DEPARTMENT, to accept responsibility for the design, construction and development of instruments involving both electronic and mechanical components, required in the Department's research programme—Prof. J. M. Bruckshaw, Geophysics Department, Imperial College of Science and Technology, London, S.W.7.

EXPERIMENTAL OFFICER or ASSISTANT EXPERIMENTAL OFFICER (plant physiologist or biochemist) to work on the nutrition of marine plankton—The Director, Scottish Marine Biological Association, Marine Station, Millport, Isle of Cumbrae, Scotland.

LECTURERS or ASSISTANT LECTURERS IN SOCIOLOGY—The Registrar, Bradford Institute of Technology, Bradford, 7.

POSTDOCTORAL FELLOW (physical chemist) IN THE DEPARTMENT OF CHEMISTRY, for work involving the measurement of the heats of chemical reactions taking place at elevated temperatures (300–1,000° C)—Dr. H. A. Skinner, Department of Chemistry, The University, Manchester, 13.

RESEARCH ASSISTANT (with an honours degree or equivalent) IN ANALYTICAL CHEMISTRY to work in conjunction with Dr. C. F. Bell, on the synthesis of co-ordination compounds of transition metals and the evaluation of their analytical uses—The Academic Registrar, Brunel College, Woodlands Avenue, Acton, London, W.3.

RESEARCH ASSISTANT (with a chemical or biochemical background) AT THE RESEARCH DEPARTMENT, Caterham, to work on aspects of tumour growth with special reference to hormone-dependent tumours—The Secretary, The Marie-Curie Memorial Foundation, 124 Sloane Street, London, S.W.1.

modern teaching depends on Unicam precision

Modern analytical techniques must be included in scientific education.
Yet students and precision instruments are often thought incompatible.
The Unicam SP600 is the ideal solution — a precision spectrophotometer of extremely robust design with time-tested components.
Thousands of SP600's are in constant use throughout the world setting the standard for spectroscopic measurement in the range 360-1000mμ.
Send for full descriptive literature today.

Some of the eighteen Unicam SP600 Spectrophotometers in use in a Teaching Laboratory at the Department of Biochemistry, University of Cambridge, are illustrated on the left.

The

Histokinette

stays on the job

Diagnostic reports to hand hours earlier than they would be with manual processing and in far greater numbers—the release of a valuable technician for other duties . . . these are the outstanding advantages of the Histokinette Automatic Tissue Processing machine. Once the Histokinette has been put into operation, it will *without supervision* go through the entire cycle of fixation, dehydration, impregnation in wax, or alternatively can be set up for the washing or staining of tissues. It can handle large numbers of specimens at the same time and while staff is off duty—speed up almost any technique by ensuring quicker and more thorough penetration by reagents.

A 24-hour clock is fitted as standard. Change over to 1 hour or 7 day cycles (*the latter of great value in double embedding and bone decalcification techniques*) is simple and rapid.

Histokinette special features include :—

- Up to 24 hours delayed start
- Double processing capacity
- One or more motor members and baskets
- Unbreakable tissue basket and containers

The Hendrey Histokinette is in general use at home and overseas

BS Precision Instruments

Immersion Refractometer

The immersion or 'dipping' refractometer, as it is sometimes known, is a versatile instrument yielding a high accuracy—0.00004 on the majority of liquids in common use in science and industry. The principal function is of a comparative nature, measuring small differences in index between similar samples. The normal range of 1.325 to 1.597 is made up using 7 interchangeable prisms, each covering a span of approximately 0.04, The first range prism (1.325 to 1.367) is also available in a water jacketted prism box as illustrated. A recent addition is a flow cell holding about 4 ml. of sample, intended for repetitive measurements where the fresh sample flushes out and replaces the previous sample. The unit is fully water jacketted for close temperature control and may also be used for continuous flow measurements.

THE FUTURE OF THE BRITISH AIRCRAFT INDUSTRY

THE great difficulties which face Defence Departments in attempting to assess the future needs of the Services for all forms of equipment were fully recognized by the sub-committee of the Estimates Committee which considered electrical and electronic equipment. Although the complexity of the techniques involved and their comparative novelty present special difficulties with electronic equipment, perhaps especially in the speed of advance, the Estimates Committee did not suggest that the position here is unique. It did suggest, however, that the present departmental arrangements contributed to the difficulties and, although the Committee did not venture into this aspect in detail, the seventh report of the Estimates Committee for the Session 1964–65 (see *Nature*, 209, 645; 1966) did not conceal its misgivings on this score, especially as regards the Ministry of Technology. It was not satisfied with the functioning in this field of either the Ministry of Aviation or the Ministry of Defence.

The key problem is the same in its essentials as that which confronted the Committee of Inquiry into the Aircraft Industry, appointed by the Ministry of Aviation, under the chairmanship of Lord Plowden, in December 1964, whose report has since been published*. That Committee was to consider the future place and organization of the aircraft industry in relation to the general economy of Britain—taking into account the demands of national defence, export prospects, the comparable industries of other countries and the relation of the industry with Government activities in the field of aviation. It was to make recommendations on any necessary steps and measures. The electronics industry was outside its terms of reference, although the interest of electronics firms in the fate of the aircraft industry is acknowledged in the Report and evidence was taken from them. Nevertheless, the terms of reference were widely drawn and the Committee recommended that some detailed aspects needed further investigation.

On the other hand, while on appointment the Committee was told that early decisions would be made on certain projects in the military aircraft programme, and the cancellation of the *P*1154 and of the *HS*681 was announced in January 1965, the fate of the *TSR*2 was not decided until April 1965. For some months, in consequence, witnesses in industry and in Government departments found it difficult to state their plans. Doubts about the military programme persisted even after April and remained unresolved until the results of the present defence review were known. In addition, several Ministerial statements about collaboration with other countries on future aircraft developments, such as the two Anglo-French projects announced in April 1965, and the aero-engine project recently negotiated with the United States, have accentuated the difficulties of the Committee.

The Report emphasizes at the outset the distinguished record of the British aircraft industry both in peace and war. For more than half a century it has made a major contribution to the defence, the economy and the technology of Britain. In recent years, setbacks and frustrations, including the cancellation of the major projects already mentioned, have diminished its prestige. In addition, British civil advanced jet aircraft have failed in general, despite their technical qualities, to realize the commercial expectations with which they were launched. Over the past 5 years, the main projects in the civil programme have together absorbed substantial private capital, as well as an increasing contribution from Government funds, and they do not, as a whole, promise a return commensurate with the investment.

The Plowden Committee was concerned with the consequent doubts about the future of the industry and its value to the community. Apart from the obscurity of the present outlook in the field of defence, it is difficult to predict with confidence the pattern of developments in civil aviation in the years ahead. The environment in which the industry operates is constantly changing and, accordingly, the Committee did not attempt to make recommendations on individual projects or on the detailed organization of the industry. It makes recommendations, however, regarding the relations between Government and the industry; but in spite of some discussion of the future of the Ministry of Aviation, it does not examine in any detail the relations between that Ministry and the Ministries of Defence or of Technology. The Committee does recommend an early review of this subject by the Government, since the efficiency of the aircraft industry is closely bound up with better arrangements for conducting aircraft business within Government departments. The Committee sought to define the basic principles which the Government and the industry should bear in mind when planning the future of the industry and when making decisions on individual projects in the coming years.

Looking first at the changing technology of the industry during the past 20 years, the Committee notes the increased performance of aircraft resulting from the gas turbine engine, the development of new materials to overcome the problems of supersonic flight, as well as the devising of new shapes with novel dispositions of wings, tail and engines. Striking advances have been made in aeronautical equipment: developments in electronics, radar and computers have revolutionized navigation and aircraft control systems, and there have also been advances in mechanical equipment and hydraulics.

All this has markedly increased the complexity of aircraft, which are now an intricate mass of electrical, electronic, hydraulic and mechanical equipment. As a result, a modern aircraft takes longer to develop and the costs of development and production are both much higher. Whereas the production cost of a *Spitfire* was about £10,000, a *Lightning* Mark I cost more than £500,000 and the *TSR*2 would have cost nearly £300 million to develop and nearly £3 million for each production aircraft. This is about twenty times more for development and ten times more for production than the *Canberra*, which the *TSR*2 was to replace. A modern sub-sonic civil air liner, including a new engine, could cost from £50 million to develop and anything from £1·5–£3 million for each

* Report of the Committee of Inquiry into the Aircraft Industry appointed by the Minister of Aviation under the Chairmanship of Lord Plowden, 1964–5. Pp. iv+139. (Cmnd. 2853.) (London: H.M.S.O., 1965.) 10*s*. net.

aeroplane, or two or three times as much as the airliner of a decade ago.

The problems of selection for customers and suppliers alike which these changes raise are rather in the speed with which technological changes succeed each other than in the character of the changes themselves. The penalties for faulty choices are heavy and, in general, fewer aircraft of each type are required than previously. The supplier of aircraft finds his resources tied up in fewer and increasingly expensive types; he is highly vulnerable if a project is suddenly cancelled. On civil projects the manufacturer himself normally finds at least half the costs of development, and if sales do not mature because some unexpected technical advance gives an advantage to a competitor, he may bear heavy losses. Timing and speed are thus increasingly important and there is a constant search for a new technological breakthrough to produce the next major advance.

This question of technology is considered more fully in a later section of the Report, in which the case for an aircraft industry is discussed. The activities of the British aircraft industry occupy some 8,600 qualified scientists, of whom 7,000 are employed in the industry itself, or 27 for 1,000 workers; this compares well with the average of 12 per 1,000 in British industry as a whole. The remaining 1,600 are engaged in aeronautical research and development or their administration in the Ministry of Aviation and its research establishments. The Plowden Committee was convinced that the new products and techniques developed by the industry found uses outside the industry and stimulated technological innovation generally. As examples of such indirect benefits or technological 'fall-out' it instanced the development of new materials, with high strength/weight properties, often coupled with resistance to high temperature, the development of digital computers, gas turbines, and high-pressure, light-weight hydraulic systems, as well as important advances in electronics, radar and radio.

While the importance of these indirect benefits was not to be doubted, it was more difficult to judge whether larger or even comparable benefits could be achieved by deploying these 8,600 scientists and technologists in other ways. For various reasons the Plowden Committee thought it improbable that any other single industry would have so pervasive an effect on the technological progress of the nation. Moreover, even if part of that effort could fruitfully be redistributed, it would not be easy to determine the objectives with assurance. Wholesale transfer of skilled research workers could not be achieved in the short or even medium term without serious loss, and the Committee had reservations as to how quickly and effectively the rest of British industry could absorb and use scientists and technicians from the aircraft industry. The caution of the Plowden Committee on this point is fully supported by the experience of the industrial research associations; it is their belief that the wider spread of technological progress in industry is limited not so much by the volume or nature of the new discoveries or advances being made by Britain's scientists and engineers, or even the areas in which they are being made, as by industry being unaware of them and unwilling to apply them.

While, therefore, the Plowden Committee concludes that disappearance of the aircraft industry, or its large and speedy contraction, would involve in the short term a significant loss to Britain's technology, it does not suggest that, in the long term, the technological 'fall-out' from the industry is a major justification for support to ensure its survival or maintenance at a particular level. The strength of this argument, moreover, depends on the general Government policy for technology; the greater the effort the Government is prepared to put into systematically encouraging the use of advanced technology throughout British industry, the less it need rely on the stimulus of the aircraft industry. Conversely, the nation cannot afford, in either the short term or long term, to tolerate weakness, whether in organization or in people, at the Ministry of Technology or at whatever Ministry may be charged with such responsibilities.

In this respect the Plowden Committee makes one constructive suggestion. It believes that arrangements to ensure that potentially valuable research reaches those British firms which could utilize it would increase the benefits from fall-out. It suggests, therefore, that the establishment of some kind of scientific clearing house merits consideration; however, it admits that the most spectacular transfers of technology will continue to result from one man's enthusiasm for a new discovery and from the determination and vision with which he applies it in apparently unrelated fields. These views, moreover, are substantially confirmed by the conclusions of a study by A. D. Little, Ltd., commissioned by the Committee, into the transfer of aerospace technology in the United States.

Some of these conclusions are worth noting. The experience in the United States provides valid examples of major transfers of technology from aerospace programmes to civilian sectors of the economy, and the existence and rapid growth of a large body of advanced technology in the aerospace sector have stimulated other sectors of the economy to consider the utility of technology in commercial life. Significant transfer of technology, however, has occurred only where a clearly recognizable correspondence was first demonstrated between technical opportunity, on one hand, and an economic or social need which could be satisfied with profit to industry, on the other.

The review also points out that a more formal and apparently comprehensive system of written communication is coming into existence in the United States to describe the developments in aerospace research, and this system is disseminated to industry at large. Much, however, remains to be done to develop the environment which can increase the efficiency of this process, and the review suggests that incentives for innovation within industry require re-examination. The transfer of technology will increase when the environment of the receiving side in industry and commerce is as open to innovation as the generating side. This is not so at present and the existing environment tends to discourage the movement of scientists and engineers with advanced knowledge of aerospace technology into other less venturesome sectors of the economy.

While such mobility is the most important factor in the transfer of technology, the A. D. Little review does not advocate the support of aerospace programmes on the ground of such stimulus to technology generally. Such stimulation is achieved more effectively by other forms of supporting civilian research and industrial innovation. The transfer of technology is no valid reason for maintaining an aircraft industry or a burdensome programme of space research. Little attention was paid to this aspect when the Report was discussed in the House of Commons on February 1. There was no suggestion that such technological transfer was a valid reason for maintaining an aircraft industry of a particular size but on the other hand, it was disappointing to find so little

attention being paid to the question of research or even to the structure of Government in so far as it affects the efficiency of the industry.

It was left for Mr. Keith Stainton to note the Committee's reference to the future of the Ministry of Aviation, but he merely pointed out that this had not been considered at all deeply by the Committee. Mr. Stainton also emphasized the importance of supporting the search for knowledge on which technical progress depends. The vital question was how this was done and he called for more analysis than was given in the Report of the areas of past research activity and general adequacy and competence to form a clear view of the future level of requirements. Even on present finance, research and development should be re-aligned but not curtailed. He urged that European co-operation should be developed on a thorough-going basis.

Mr. J. Stonehouse, Parliamentary Secretary to the Ministry of Aviation, replying on the debate, clearly recognized the importance of research. This was one reason why it was essential to widen the market for British aircraft, for example, by collaborative projects with our allies. At present the industry could not sustain its research and development costs and, as the Plowden Committee pointed out, was looking to the Government for a larger contribution than in the past towards the launching costs of any new project. Over the years between 1960 and 1963, research and development expenditure by the Government in the British aircraft industry on aircraft, excluding guided weapons, averaged about £100 million and total aircraft sales about £320 million. In the United States over the same period, expenditure on research and development of military aircraft averaged 635 million dollars and on procurement 5,500 million dollars a year. The Committee's rough calculations suggest that in recent years the degree of Government support given to the aircraft industry has been substantially higher than that given to British industry in general. Moreover, the higher the cost of research and development for an aircraft type, the more the price of the British version is likely to exceed that of the American.

The Plowden Committee's conclusion that the effort to establish a self-supporting British civil aircraft industry had not yet succeeded was not challenged in the debate in the House of Commons. The debate was in fact more especially concerned with the presentation in Section IV of the Report of the case for an aircraft industry. As already noted, the Plowden Committee did not base this on the transfer of technology, and while it thought that the defence benefit offered by the industry in affording an extra measure of national independence was of value at the present time, it also thought that the evidence suggested that the value of the benefit was likely to decrease and its cost increase. Nor did it consider that a case could be made out for the industry in terms of employment. It believes that new jobs would fairly quickly be found for workers from the aircraft industry if released, and, while a successful industry can make a genuine contribution to the nation's welfare, it does not regard this argument as validating the case for any particular level of support unless the very survival of the industry were in question.

From the point of view of stability the Plowden Committee concedes that there might be a case for some support to maintain the aircraft industry at a particular, lower level so that past failures would not debar it from achieving future success. Basic to this case, however, is a realistic prospect in the long run of successes outweighing failures so that such support could then be withdrawn. The Committee does not believe that in the long run the country would suffer from a major contraction in the industry, provided it was accompanied by adequate Government policies for technology. Nevertheless, Britain would suffer a serious loss if policies were followed which resulted in the speedy withering away of the industry, and the Committee does not believe that, in the long term, the benefits conferred by the aircraft industry will be so large or unique as to make it worth maintaining in existence regardless of cost; still less doing so at its present or at any particular level. Accordingly a coherent set of policies is required which offers the prospect of reducing support, the basic problem being to improve the relation between sales of the industry's products, their development and their initial production costs.

Four main policies are regarded as contributing to this. First, Britain should collaborate on a comprehensive range of military and civil projects with overseas partners. Secondly, these projects should be those for which development costs are reasonable in relation to the expected market. Thirdly, where development costs are disproportionate, as with the largest and most complex military aircraft and guided weapons, essential needs should be met by purchases from the United States. Fourthly, the industry's exports must be increased. In the view of the Committee a shift from total dependence on home production for Britain's defence needs is indispensable to these policies, and it appears that the Ministry of Defence is now ready to make such a shift.

Discussing next the possibilities of widening the market, the Committee observes that, while air traffic has grown year by year, the annual rate of growth has been declining since the Second World War and in the past few years has fallen to 12 per cent. Available evidence points to some further slow decline in the future. The increasing world demand offers little prospect for substantially increased sales for the British industry on its own, and the home military demand is unlikely to increase and may well fall. On collaboration with the United States the report emphasizes the free and intensive exchange of military scientific information encouraged by the close alliance between the two countries. Although on civil aircraft the exchanges are more restricted in view of the keen commercial competition, yet the British aircraft industry would be the poorer if the general flow of information were impeded.

Britain has also benefited from aviation research and development which successive American Governments have encouraged among their allies in Western Europe since the Second World War, often with generous financial assistance. The United States has shown a high regard for the inventiveness of Britain's scientists and several joint research and development projects have been launched between the two countries. There is little doubt that in those areas where Britain has a lead, or the promise of a lead, over the rest of the world, the United States Government will continue to encourage industry to co-operate with us in research and development.

While some, though not many, further joint projects may be expected, the United States has no over-riding need for a partnership in aircraft development and production. The technical resources of the American industry can meet all that country's main needs, and the domestic demand alone is normally sufficient to make production economic. Accordingly, the Plowden Committee believes that there is no likelihood of any agreement being reached on a comprehensive joint aircraft research and develop-

ment programme between British and American manufacturers. However, it considers that there should be scope for occasional worthwhile schemes for joint research and development as well as for the wider use of British engines and equipment in United States aircraft.
